ABSTRACT. An 8-month-old, Nubian wether with a history of systemic illness was euthanatized for a pathological examination. At necropsy, the presence of disseminated abscessation and cellulitis in the limbs was noted. Other postmortem findings associated with the visceral disease in this animal included multiple abscess lesions, mainly in the lungs, kidneys, phalanxes and vertebrae. Histopathologically, lesions of arteriolitis were found as evidenced by bacterial embolisms in pulmonary and renal arteriola, indicating a bacteremia in the patient. Arcanobacterium pyogenes was consistently isolated from 8 lesions of abscessations, including the lesions of subcutaneous abscesses as well as bone marrow abscess in phalanxes and thoracic vertebrae. This is the first published report of disseminated arcanobacterial infection with bone marrow abscess of both the phalanxes and vertebræ in goat.

KEY WORDS: abscessation, Arcanobacterium pyogenes, bone marrow abscess, goat.

---

Arcanobacterium pyogenes (formerly named Actinomyces pyogenes and Corynebacterium pyogenes) [19] is associated with production of abscesses and pus, particularly in ruminants [10, 16]. This organism is one of the several bacterial species that constitute the common resident on the mucosa of urogenital tract, upper respiratory tract and ruminal wall in ruminants and swine [4, 7]. A. pyogenes is also an opportunistic pathogen which may survive in humid environment for up to 10 months [16] and can disseminate to cause suppurative infections involving the skin, joints, lymph nodes and feet [4, 7, 10, 16] as well as a variety of visceral lesions such as liver abscess, kidney abscess, intracranial abscess, purulent pneumonia, osteomyelitis, and pyometra in several animal species [7, 10, 15, 17, 20, 21]. Corynebacteria spp. have been isolated from the udder infected with mastitis in ewes, whereas 10% (5/50) of them were recognized as A. pyogenes [8]. The present report describes the clinical presentation and pathological findings in a Nubian goat with disseminated abscessation complicated with bone marrow abscess due to A. pyogenes infection.

The herd was comprised of approximately 200 Nubian goats of varying ages. All the goats were maintained under uniform feeding and were generally in good body condition all year round. The animals were group-housed under intensive system of rearing confined in several identical pens (3 × 3 m) with slatted floor. On average, 15 goats were raised in a pen. The owner reported that 5 goats had progressive signs of multiple fluctuating swellings on limbs, which had gradually enlarged over a period of 3–4 weeks. As none of the 5 goats responded positively to daily treatment with lincomycin and corticosteriod, also presenting recumbency with abnormal general condition, 4 of them were culled. The other, an 8-month-old, 37 kg, Nubian wether was submitted to the hospital for evaluation of this disease.

On presentation, the goat was recumbent and showed signs of dullness with pyrexia up to 41.1°C, multiple abscess lesions under the skin of the limbs. Over-growing and cracks of the hooves were noted. Abnormal findings during physical examination included an estimated dehydration of 3–5%, absence of rumen motility and prolonged capillary refill time (>3 sec). There was no evidence of wounds on the body.

Blood abnormalities included severe macrocytic, hypochromic anemia with marked thrombocytopenia, leucocytosis (20,100 leucocytes/µl) and an absolute neutrophilia (8,844 neutrophils/µl) with a moderate left shift (bands 1,005 cells/µl). There were markedly increased activities of aspartate aminotransferase (166.6 U/l), lactate dehydrogenase (527 U/l), alkaline phosphatase (151 U/l), and creatine kinase (90 U/l). The levels of albumin (2.0 g/dl) and A/G ratio (0.42) were lower than normal, as were the concentrations of serum calcium (7.0 mg/dl) and magnesium (0.8 mg/dl). The differential diagnosis included caseous lymphadenitis, bacterial polyarthitis and Mycoplasma arthritis. Medical intervention was not an option and the goat was euthanatized for a pathological examination with the owner’s consent.

Postmortem examination revealed the presence of cellulitis extending from carpus to shoulder of the right forelimb as well as in the area of metatarsus of the right hindlimb, which was completely filled with large amounts of whitish-yellow purulent exudates between the epidermis and muscularis. Multiple swellings as a result of pus accumulation in the area of the shoulder on the left forelimb were seen, in which...
the arthrodial cartilage was invaded by evidence of fibrinous adhesion. Totally, 4.8 liters of pus was drained from the cellulitis and abscess lesions. The feet showed severe sole ulceration with related bone marrow abscess in 2nd and 3rd phalanxes, in which purulent exudate (arrows) was noted. Other postmortem findings associated with the visceral disease in this animal included multiple abscess lesions, mainly in the lungs (pleurobronchopneumonia), kidneys and vertebrae starting from the 4th cervical vertebra to the 4th thoracic vertebra (Fig. 2). The lymph nodes involved in the areas of abscessations were grossly enlarged. At histopathological examination, lesions of arteriolitis packed with thrombi and scattered bacterial clumps were noted throughout the lung (Fig. 3). Mild congestion and emphysema were seen in the pulmonary parenchyma, while widespread lesions of necrotizing bronchitis were evident by large amount of bacterial clumps and fibrinoid material. Multifocal wedge shaped infarcts were mostly found at the end of the thrombolized arcuate arteries. Additionally, multiple infarctions were present in the cortex of the kidney (Fig. 4). Well demarcated necrotic renal infarctions were filled with neutrophils, cellular debris, and bacterial clumps. Arterial thrombosis was found as evidenced by bacterial embolisms in pulmonary and renal arteriola which were predominantly infiltrated with numerous neutrophils in the arteriolar walls. Gram-stained impression smears from the bone marrow revealed numerous rod shaped Gram-positive bacteria, occurring single or in clumps, mixed with neutrophils and necrotic trabecula indicating bone marrow

abscess in the vertebra and phalanxes. Swab specimens for bacterial culture were obtained from 8 lesions of abscessations, including the lesions of subcutaneous abscesses and bone marrows in phalanxes and thoracic vertebrae. All the swabs specimens yielded a pure, heavy growth of *A. pyogenes*, which was sensitive to cephalothin, flofenicol and trimethoprim/sulfamethoxazole according to related disc agar diffusion antimicrobial susceptibility test by Clinical and Laboratory Standards Institute (CLSI). The results of bacterial culture were consistent with the findings of Gram-stained smear from the swabs and the bone marrow smears, showing clusters of Gram-positive rods. However, there was a paucity of histopathological evidence of the bone specimen and no organism was isolated from the blood sample. Based on the pathological and microbiological findings, a case of disseminated abscessation complicated with bone marrow abscess due to *A. pyogenes* infection was diagnosed.

A variety of organisms causing subcutaneous abscess have been isolated in goats, such as *Corynebacterium pseudotuberculosis*, *A. pyogenes*, *Escherichia coli*, and *Staphylococcus* and Streptococcal species [24]. The organisms may enter the blood stream and cause bacteremia, abscesses and suppurative lesions in various tissue and organs [7]. Abscessation results from infection with *A. pyogenes*, which usually gains entry through puncture wounds or abrasions of the skin, showing lesions particularly on the head and body [10, 24]. However, no wound was found on the body of this wether, except the sole ulceration in hooves. Foot abscessation may occur as a result of invasion of *Fusobacterium necrophorum*, which, along with *A. pyogenes*, is usually responsible for hoof infection in small ruminant animals [16, 24, 25], however, *F. necrophorum* from the hoof lesions of this wether was not isolated.

Pyogenic infection and abscess formation have been previously reported in sheep which affected meat quality and caused the death of the suffering animals, in which, *A. pyogenes* infection had a prevalence of 5.9% in this sheep flock [5]. In this case, because the purulent exudates accumulated in the deep subcutaneous tissue and muscle, the spread of abscesses contributed to contamination of goats meat, causing the threat to the public hygiene and food safety. Culling of affected goats was suggested. It is suggested that prompt medical intervention at the early stage of abscess formation is necessary to bring about a favourable outcome [24].

Bacterial infection of the bones is rare in goats [10, 24]. A previous report has described a case of osteomyelitis of the ribs associated with *Corynebacterium renale* in a goat [1]. In the present case, pathological examinations revealed enlargement of the regional lymph nodes as well as bacterial embolisms in pulmonary and renal arteriola, indicating a bacteremia in the patient. The pathological evidences suggested that both lesions of bone marrow abscess in vertebræ and phalanxes occurred secondary to haematogenous spread from disseminated abscessation, although no organism was isolated from the blood sample.

Since we can only show the bacteriological evidence of the bone marrow smear, it could be speculated reasonably, that osteomyelitis was the case in the phalanxes and thoracic vertebræ. Osteomyelitis is believed to generally result from the hematogenous spread of a remote focus of infection or post-traumatic contamination of microbial seeding of the bone in humans, cattle and horses [9, 11, 13, 22, 27]. *Staphylococcus aureus* is the most prevalent causative microorganism of hematogenous osteomyelitis in humans [13, 22], which occurs predominately in children [6, 14, 22]. In the majority of cases, vertebral osteomyelitis is hematogenous in origin [2, 22], sources of bacteremia include a trivial skin infection, infective endocarditis, or a serious infection of the respiratory, gastrointestinal or genitourinary tracts [14, 22]. In cattle, salmonella and *Corynebacterium pyogenes* were mostly isolated from the bone lesions of epiphysal and physeal osteomyelitis, respectively [9]. In horses, enterobacteriaceae are most commonly isolated in cases of hematogenous osteomyelitis in foals as a result of sepsis, which occurs mostly in a joint, epiphysis, or physis [11]. Additionally, cases of mycotic osteomyelitis presenting lesions in the proximal phalanx, rib and metacarpophalangeal joint, have also been reported in young horses [18, 26].

The bacterial colonization in the bone is required in order to initiate infection [12]. Bacteria can adhere to tissues by binding host proteins, including fibrinogen, fibronectin and collagen [6]. For instance, collagen-binding adhesin (Cna) makes an important contribution to the ability of *S. aureus* to bind collagen, which is encoded by a gene (Cna) of *S. aureus*, but not present in most strains [6, 23]. This function leads to the bacterial attachment and formation of biofilm with the subsequent growth of sessile bacteria on the host tissue [11, 12, 23]. However, it is not known whether *A. pyogenes* is consistent with the two-stage process described above to establish infection in bone.

It has been reported that *A. pyogenes* isolated from cattle and swine was fully sensitive to benzylpenicillin and ampicillin, moderately sensitive to ceftriaxone, cefepirin, and resistant to dihydrostreptomycin and oxytetracycline [29]. A similar result has been found by Trinh et al. [28], where 70.6% of porcine, but only 25.9% of bovine *A. pyogenes* isolates were resistant to tetracyclines. Our result indicated that *A. pyogenes* isolate was resistant to penicillin, oxytetracycline, ceftriaxone, enrofloxacin, and lincomycin, and was sensitive to cephalothin, flofenicol and trimethoprim/sulfamethoxazole. Frequent use of antibiotics may lead to the emergence of resistant *A. pyogenes* strains and additionally the potential for antibiotic residues in meat.

We speculate that the sporadic outbreak as a result of high rearing density in this flock leading to intimate contact among goats, which predisposed the animals to the *A. pyogenes* infection. Such a stress factor probably affected the animal’s resistance, contributing to the spread of the pathogen to subcutaneous tissues and thence to other viscera. Control measures in this herd might include decreasing overall rearing density, hoof care and trimming, removing any sharp pointed objects in the barn, and maintaining goats.
in clean and dry areas. The case was followed up by culling 2 goats suffering from subcutaneous abscesses and mastitis caused by \textit{A. pyogenes}, respectively. The disease outbreak has been completely controlled at the following farm visiting.

Although the pathological lesions of this case were in line with what has been previously described in ruminants [3, 5, 7, 16], the authors believe that this is the first published report of disseminated arcanobacterial infection with bone marrow abscess of both the phalanxes and vertebrae in goat.

ACKNOWLEDGMENT(S). The authors would like to acknowledge the assistance of Miss A. Jack for the English revision.
