Abstract. Pathological studies were carried out on laryngotracheal and conjunctival lesions caused by experimental infection with so-called Asian type Newcastle disease virus. In them, strain 2440 of the virus was inoculated into two groups of chickens by the intratracheal and intra-ocular route. The same symptoms and gross lesions as those of the acute type in field outbreaks were observed in the birds of both groups during 3 to 6 days after inoculation. Prominent necrosis of the epithelium and lymphatic areas and mild to moderate proliferation of lymphoid cells were seen as characteristic changes in the organs studied. The course of epithelial necrosis was initiated by vacuolation of the cytoplasm, followed by the appearance of eosinophilic inclusions and the formation of a network inside the cytoplasm and terminated by the disintegration of epithelial cells into debris. Necrosis of the lymphoid area was similar to the change of lymphatic organs previously reported by this author.

Newcastle disease (ND) was first described by Doyle [1] and has been examined pathologically by various authors from different points of view. Jungherr et al. [6] made pathological comparison in details between fowl plague and so-called Asian type ND. Similar reports on pathological investigation of Asian type ND have been published by several workers [2-5, 10, 12].

There has been, however, few works on pathological observation on laryngotracheal and conjunctival lesions caused by Asian type ND virus infection, because this virus might have been recognized as having an enterotropic nature.

Kawasaki et al. [9] reported that under gross observation hemorrhage was sometimes noticed in the conjunctiva of natu-

rally infected chickens in addition to the occurrence of laryngotracheal and cloacal lesions. Recently, it was confirmed that birds infected experimentally with Asian type ND virus often associated with laryngotracheal lesions characterized by hemorrhage, necrosis and ulcer [11].

There has been, however, no reports describing the transition of laryngotracheal and conjunctival changes caused by Asian type ND virus infection.

The purpose of this paper is to report the laryngotracheal and conjunctival changes in chickens experimentally infected with Asian type ND virus. Pathological observation and immunofluorescent studies were made.

Materials and Methods

1. Materials

Virus: ND virus used in the present study was strain 2440 which had been isolated from a field outbreak in 1967 at the author's station and identified as ND virus. The virus had been passed 6 times through chicken embryos before this experiment.

Chickens: Seventy-two White-leghorn chickens, 36 days old, were used. The hemagglutination-inhibition (HI) test was performed before the experiment and HI titers were found to be undetectable.

Direct fluorescent antibody technique: The direct fluorescent antibody technique of Kawasaki [8] was applied by using fluorescent-globulin prepared from chickens which had been infected with and recovered from Asian type ND.

2. Methods

The suspension of virus, strain 2440, was calculated to have an infective titer of $10^{8.5}$ TCID₅₀/0.1 ml. Then a virus inoculum was prepared by diluting the suspension to 1:1,000 with PBS (pH 7.0) containing 200 mcg of dihydrostreptomycin and 200 i.u. of penicillin-G/1.0 ml.

Seventy-two birds were divided into 2 groups of 36 birds each and placed separately in special isolation units.

tion units.

Each bird of one group received intratracheal inoculation with 0.1 ml of the inoculum. On the same day each bird of the other group was inoculated intraocularly (into both eyes) with 0.05 ml/eye of the inoculum.

Clinical observation was made for 6 days post-inoculation. On each day of experiment, 4 to 6 birds were randomly selected from each group and subjected to necropsy. After gross observation was made, portions of the larynx, trachea and conjunctiva were taken and fixed in a 10% formalin solution. Thin sections of these portions were stained with hematoxylin and eosin for histopathological examination. The same tissues were also placed in N-hexan refrigerated with a mixture of solid carbon dioxide and acetone, and sectioned by a cryostat for immunofluorescent examination.

Results

1. Clinical symptoms and gross pathology

Clinical symptoms and gross changes observed were generally identical to those reported in typical Asian-type ND infection. Symptoms noticed were green diarrhea, depression, tic and cyanosis of the comb.

Gross lesions detected were of hemorrhagic and necrotic nature. In chickens killed 4, 5 and 6 days after inoculation, occasional diphtheric involvement of the larynx, trachea and conjunctiva was noticed, as well as typical hemorrhagic and/or necrotic lesions in the gastrointestinal and lymphatic organs, such as the bursa of Fabricius, thymus and spleen.

Symptom and gross lesions at the sites studied of every bird are summarized in Table 1.

2. Micropathology and immunofluorescent studies

Larynx

Micropathology: Laryngeal lesions in birds having received intratracheal inoculation were similar to those induced intra-ocularly. Described are findings in birds injected intratracheally.

As shown in Table 2, the earliest lesions appeared in the larynx where lymphatic tissues are normally abundant. This was followed by the appearance of lesions in the trachea descending from the upper part to the lower part.

Changes 1 and 2 days after inoculation

The initial change was characterized by vascular congestion and small foci of lymphatic cell-necrosis in lymphoid area. Sometimes edematous swelling was observed partially in the epithelium and mucous gland. A few heterophils were disseminated in those areas.

Changes at 3 days

Initial changes in the mucous gland were not noticed. Some parts of the gland involved fell into necrosis and vanished. Progress of degeneration in epithelial cells varied. Slightly degenerated cytoplasm swelled edematously and contained small

vacuoles. The nuclear membrane of such cells stained densely with hematoxylin. The cytoplasm of moderately affected cells swelled edematously and contained large vacuoles. As a result, the involved cytoplasm was arranged like a network. The involved cells often contained eosinophilic inclusions, which looked to be round, club-like or amorphous inside the cytoplasm. In the most seriously affected cells, the cell-boundry disappeared and the cells themselves looked like basophilic or eosinophilic granules. Desquamation of the affected epithelium was often noted.

In the lymphoid area, lymphatic cells almost vanished and reticuloendothelial (RE) cells remained or proliferated. Degeneration and coagulation necrosis occurred partially in small blood vessels accompanied with fibrinoid masses stained densely with eosin in the perivascular area.

Changes at 4, 5 and 6 days

The lesions found were similar to those observed 3 days after inoculation. There was no difference in progress of lesions among 6 birds killed on the same day.

Most part of the larynx of chickens sacrificed 5 and 6 days after inoculation showed marked desquamation or lack of the epithelium. Progressed changes were characterized by complete necrosis in the epithelial layer and lymphoid area. In contrast, there were some moderate cases in which most epithelium was retained and slight perivascular proliferation of immature lymphoid cells was observed.

In some cases, necrosis occurred in the striated muscle layer surrounding the larynx.

Immunofluorescent findings: Disseminated fluorescent granules were observed in the cytoplasm of gland cells and the upper side of epithelial cells in samples collected 2 days after inoculation.

Three days after inoculation, cytoplasmic fluorescent granules appeared brightly. The fluorescence was brighter in gland cells than in epithelial cells. Many fluorescent foci were disseminated in the lymphoid area. Fluorescence seemed to be present in the cytoplasm of RE cells.

Immunofluorescent findings on 4-day samples were similar to those on 3-day samples, except that less fluorescence was seen in the epithelium because of its desquamation.

Trachea

Microscopical lesions and immunofluorescent findings in the trachea were similar to those in the involved larynx.

Conjunctiva

Micropathology: Microscopic changes in the conjunctiva in birds inoculated intracocularly are described.

Changes 1 and 2 days after inoculation

There were no marked changes in the epithelial layer, except slight vacuole-formation inside the cytoplasm of epithelial cells. Although there was no distinct lesion in the epithelial layer, small and localized necrosis consisted of debris of lymphatic cells was found in the submucosal lymphoid area. Mild infiltration or proliferation of lymphoid cells was noted in the perivascular area. Heterophils were scattered throughout the lymphoid area and the epithelial layer.

In this stage, the lesion of the conjunctiva was generally restricted to the site of the Fornix conjunctivae.

Changes at 3 days

Moderate vacuole-formation in the cytoplasm was present in epithelial cells. The nuclear membrane of the cells stained densely with hematoxylin. Mild to moderate vanishment of lymphatic cells was

noticed in the lymphoid area accompanied with many heterophils disseminated.

Changes at 4 days

Marked vacuolation in the cytoplasm was found in most epithelial cells. Desquamation of these cells was often observed. Eosinophilic inclusions resembling those in the laryngotracheal epithelium were present inside the cytoplasm. The nuclear membrane of these cells was stained densely with hematoxylin. In the epithelial layer, small spaces were often formed and sometimes contained necrotic products.

In the most severely affected cases, epithelial cells disappeared or disintegrated in the epithelial layer, and lymphatic cells vanished from the lymphoid area. Sometimes localized necrosis also destroyed RE cells. Many heterophils were disseminated throughout the epithelial layer and the

lymphoid area. Partial necrosis of small blood vessels was often found. Homologous, eosinophilic and amorphous masses, which seemed to be fibrinoid, were deposited in the perivascular area. Marked hemorrhage was often found in the adjacent area.

Changes at 5 and 6 days

In addition to similar lesions observed in samples collected at 4 days, small necrotic foci were found in the squamous-cell layer.

Immunofluorescent findings: Three days after inoculation, fluorescent granules were found in the cytoplasm of some epithelial cells. A bright fluorescence was observed in the lymphoid areas of the conjunctiva 3 and 4 days after inoculation. The fluorescence in the lymphoid area seemed to be present in the cytoplasm of RE cells. Four days after inoculation the fluorescence of the lymphoid area was distributed through-

Fig. 1.

Situation of lesions and fluorescence in laryngotrachea and conjunctiva: Laryngotracheal lesions of the intratracheal inoculation group were found prior to the lesions in the conjunctiva, and vice versa in the intraocular inoculation group (Table 3).

In the fluorescent findings of the intratracheal inoculation group, the presence of viral antigen in the laryngotrachea was confirmed from the initial stage of infection. On the other hand, the conjunctival fluorescence of this group was not found on the same stage of infection. Fluorescence of detected sites was generally faint in intra-ocular inoculation group comparing with the intra-tracheal inoculation group (Table 4).
