Summary: Introduction: The gall bladder (GB) is a storage reservoir that allows bile acids to be delivered in a high concentration. The quadrate (QL) and caudate lobes (CL) are functional parts of the liver. The knowledge of the gross and developmental anatomy of GB and CL and QL of liver is important for surgeons who operate in this region. The present study was conducted to examine the developmental sequence and morphometry of the GB, and CL and QL of liver.

Materials and Methods: In the present cross sectional study the parameters measured were length of GB from the neck to the lowest point on the fundus, and the length and width of QL and CL measured at the midpoint. The data was analyzed statistically and the various parameters were correlated using Pearson’s correlation.

Results: There was a statistically significant correlation indicating that the growth of GB, QL and CL was proportional to the gestational age (GA). The variations in the morphology of the GB were also noted. In two specimens it was found that the GB was embedded partially in the substance of the liver and failed to reach the inferior border of the liver.

Conclusion: The regression equations calculated in the study provide a tool to estimate the lengths of GB, QL and CL prenatally.

Key words gall bladder, caudate lobe, quadrate lobe, developmental anatomy, porta hepatis

INTRODUCTION

The gall bladder (GB) lies on the undersurface of the right lobe of the liver [1, 2]. It is a pear-shaped distensible structure consisting of a fundus, body and neck. The GB receives its blood supply from the cystic artery, which is a branch from the right hepatic artery [3, 4].

The quadrate lobe (QL) and caudate lobe (CL) are functional parts of the right lobe of the liver [2]. The caudate lobe, also known as the posterior hepatic segment, is situated between the ligamentum venosum, the porta and the fossa for the inferior vena cava. It is supplied by both the right and left branches of the portal vein [2]. Occlusion of hepatic venous outflow may lead to Budd-Chiari syndrome, resulting in hypertrophy of the CL [5]. The quadrate lobe of the liver is bounded by the fossa for gall bladder, fissure for the ligamentum teres, porta hepatis and caudate process and the inferior border of liver [6].

Embryologically, the liver develops from a hepatic bud that arises from endoderm in the region of the junction of the foregut and yolk sac at the fourteen-somite stage. The hepatic bud grows within the mesogastrium, reaches the septum transversum and divides into right and left branches. Each branch gives rise to clusters of liver cells forming two solid masses which later give rise to the right and left lobes of liver [6]. Anomalies related to excessive development of the liver may lead to the formation of accessory lobes, which may carry the risk of torsion [3].

Abbreviations: CL, caudate lobe; CRL, Crown rump length; GA, gestational age; GB, gall bladder; IEC, Institutional Ethics Committee; QL, quadrate lobe.
Knowledge of the gross and developmental anatomy of the GB, and CL and QL of liver is growing in importance as congenital and acquired diseases of the GB are increasing. The present study was conducted to determine the length, width and variations of the GB, and CL and QL of liver, during antenatal development.

MATERIALS AND METHODS

The present study was conducted at the Department of Anatomy, Kasturba Medical College, Manipal using 18 formalin fixed fetuses with gestational age (GA) ranging from 12 to 36 weeks without any congenital anomaly. The study was carried out for a period of 6 months. The fetuses were collected from the Department of Obstetrics and Gynecology, Kasturba Hospital. Crown rump length (CRL) of the fetuses was measured between the vertex of the scalp and the midpoint of apices of the buttocks. The liver and gallbladder were removed. Livers and gallbladders with visible congenital malformations were excluded from the study. The study was approved by the Institutional Ethics Committee (IEC) of Kasturba Medical College, Manipal, India. The following parameters were measured using digital calipers.

1. Length of GB was measured from the neck to the lowest point on the fundus
2. Length and width of QL, measured from its midpoint
3. Length and width of CL, measured from its midpoint

The parameters measured are shown in Figs A-1, 1a and 1b.

The data was analyzed statistically using SPSS version 16 and the various parameters were correlated using Pearson’s correlation.

RESULTS

The GA of the fetuses included in the study ranged from 12 to 36 weeks. The CRL ranged from 16.5cm to 35.5cm. The descriptive statistics of the measured parameters are shown in Table 1. The sample was assessed using Kolmogorov Smirnov’s test for the normality of distribution and Levene’s test for the homogeneity of variance. As the sample showed a normal distribution, parametric tests were used for the further statistical analysis.

Pearson’s correlation was applied to assess the correlation of the parameters measured with GA and CRL (Table 2). There was a statistical significant correlation indicating that the growth of GB, QL and CL was proportional to the GA.

As there was a statistically significant correlation between the GA and the measured parameters, linear regression was used to construct the regression equations. GB length, QL length, and QL width could be calculated in mm as follows. Regression equations were calculated for the 18 specimens included in the study.

Length of GB = 0.36×GA + 10.1
Length of QL = 0.66×GA + 6.13
Width of QL = 0.2×GA + 6.37

Variations in the morphology of the GB were also noted. At term the GB was fully grown and the fundus was at the level of the inferior border of the liver. In two specimens it was found that the GB was embed-
ded partially in the substance of the liver and failed to reach the inferior border of the liver at term (Fig 2a and 2b).

Fig. 2. In a term fetus, GB embedded partially within the substance of liver and the fundus fails to reach the inferior border of the liver (arrow).

DISCUSSION
The fetal GB seen during antenatal sonography presents as an anechoic, elliptical structure to the right of the intrahepatic umbilical vein. As gestation advances, the gall bladder grows in a predictable fashion [11, 12]. A large gall bladder would be a postnatal feature of trisomy [13]. Therefore size evaluation of the fetal gall bladder may be an indicator of the risk of chromosomal aneuploidy [13].

In a fetal study by Sangeetha et al the CRL ranged from 51-338 mm. The range for GA was 70-262 days. The range for GB length was 11.1-33.5 mm. The mean value of GB length was 17.630±6.5412 mm [14].
In the present study the average length of GB was 18.6±4.4 mm, which was similar to the previous results.

Some authors have observed that the fetal GB can be visualised from early in the second trimester; hence non-visualization of the fetal GB from this point may indicate cystic fibrosis, gall bladder atresia, and biliary atresia [15, 16].

In a study done by Albay et al., the lengths of CL observed in the three trimesters were 5±1, 10±3, 16±3 and 18±4 mm. CL widths were 4±1, 7±2, 11±2 and 13±3 mm. QL lengths were 8±1, 14±4, 23±6 and 29±5 mm. QL widths were 4±1, 8±3, 13±4 and 17±5 mm in the first, second, third and full term respectively. He demonstrated a high positive correlation between the sizes of the CL and the QL, and GA. Comparisons of these parameters among groups revealed no significant difference in the height of the CL between the 3rd and 4th groups, while the widths of the caudate and QL as well as the lengths of the QL demonstrated a significant increase (p<0.05). There were no differences in the parameters between males and females. There was a statistically significant relationship between the size of gallbladder and the GA [17].

Murao et al. found a high correlation between liver size and other parameters between the 19th week and term, and concluded that liver size could be used to assess fetal growth [18]. Roberts et al studied the importance of diagnosis and follow-up of gestational diabetes and hepatomegaly and observed that the length of the fetal liver was 12% greater in diabetic pregnancies at 18 weeks when compared to the non-diabetic pregnancies [19].

The possibility of abnormal liver has to be kept in mind when an abdominal mass is encountered. In the present study, the variations in the morphology of the GB were also noted. In two specimens it was found that the GB was embedded partially in the substance of the liver and failed to reach its lower border.

In a study by Aktan et al., the left lobe was absent in one case and the caudate lobe was absent in 4 cases [20]. The knowledge of liver anomalies, especially of the CL and QL of liver is important to achieve a correct preoperative diagnosis, and because it will help the surgeon in planning biliary surgery or a portosystemic anastomosis. Many studies suggest that fetal liver size measurements are valuable tools in detecting intruterine growth retardation, gestational diabetes, intrauterine infections, isoimmunization, fetal heart failure, neoplasms, certain metabolic diseases and fetal macromasias and their follow-up [21-23].

A thorough knowledge of the anatomy of the fetal liver and gall bladder is essential for the diagnosis and treatment of various disorders, and this study will be helpful to surgeons who work in this region. In the present study, the parameters were not compared between male and female fetuses as there were only two female fetuses were available. The regression equation was not calculated for the parameters of CL as the authors were unable to measure the parameters in all the specimens due to tissue damage.

As several studies about the morphology of the fetal liver are available in the literature, the current study concentrated only on the CL and QL and correlated them with the GA.

CONCLUSION

The regression equations calculated in this study provide a tool for estimating the lengths of GB, QL and CL prenatally. The findings in this study would be useful for ultrasound investigations of the liver and furthermore, the data will be helpful in the evaluation of fetal autopsy material.
