Abstract

A 51-year-old woman had been followed up for 10 years for recurrence of pilocytic astrocytoma 5 years after the initial treatment consisting of subtotal resection, chemotherapy, and radiation therapy. The patient presented with sudden onset of headache and vomiting. Computed tomography and T2*-weight ed magnetic resonance imaging revealed hemorrhage in the tumor located in the right basal ganglia, thalamus, and hypothalamus. She underwent gross total resection of the lesion. Histological examination confirmed recurrent pilocytic astrocytoma with organizing hematoma and granulation tissue. Although neither symptomatic hemorrhage nor late benign recurrence is common, careful long-term follow up is necessary for patients with pilocytic astrocytoma.

Key words: supratentorial astrocytoma, pilocytic astrocytoma, hemorrhage, recurrence, magnetic resonance imaging

Introduction

Pilocytic astrocytoma is a benign tumor that most commonly occurs during the first two decades of life.5) These tumors occur at all levels of the neuraxis, including the cerebellum, optic nerve, optic chiasm/hypothalamus, thalamus, brain stem, spinal cord, and cerebral hemisphere containing the basal ganglia.5) Pilocytic astrocytoma is a slow-growing tumor, and gross total or subtotal resection without adjuvant therapy results in good outcome in most patients, although several cases of late recurrence have been described, including as long as 36 and 45 years after surgical treatment.1,4,6,9,14,29) Pilocytic astrocytomas are frequently associated with cysts that occasionally contain xanthochromic or brown fluid suggesting old hemorrhage.5,30) However, symptomatic hemorrhage related to pilocytic astrocytoma is rare.

We describe a case of recurrent pilocytic astrocytoma with organizing hematoma and granulation tissue manifesting as symptomatic intratumoral hemorrhage 15 years after the initial treatment.

Case Report

A 35-year-old woman presented with progressive muscle weakness of the left lower limb in 1986. Computed tomography (CT) revealed a cystic lesion with an enhanced portion located in the right temporal lobe, basal ganglia, and hypothalamus (Fig. 1A, B). She was referred to our hospital, and underwent subtotal resection of the tumor and placement of an Ommaya reservoir in 1987 (Fig. 1C). The mural nodule was not well demarcated so could not be resected completely. Histological examination revealed a biphasic pattern of growth, with compact portions consisting of bipolar astrocytic tumor cells associated with Rosenthal fibers, and cystic zones comprised of multipolar cells (Fig. 2A, B). The diagnosis was pilocytic astrocytoma. Adjuvant therapy consisting of chemotherapy with 1-(4-amino-2-methyl-5-pyrimidinyl)-methyl-3(2-chlorethyl)-3-nitrosourea (ACNU) and vincristine and radiation ther-
Hemorrhage Associated With Pilocytic Astrocytoma

apy (50 Gy) was performed. She was discharged in 1987 with left hemiparesis, left hemisensory disturbance, and left homonymous hemianopsia.

CT revealed no mass lesion with enhancement 18 months after the treatment. However, follow-up CT demonstrated a multicystic lesion with partial enhancement, indicating recurrence of pilocytic astrocytoma, 5 years after the initial treatment (Fig. 1D). Further follow-up CT and magnetic resonance (MR) imaging revealed slow growth of the tumor without neurological worsening. Since the patient exhibited allergic responses to various drugs possibly required after surgical treatment, including anticonvulsants and antibiotics, we decided to observe the patient carefully as long as no neurological deterioration occurred. The patient had not experienced symptoms attributable to intracranial bleeding for 10 years.

The patient suffered sudden onset of severe headache and vomiting on January 20, 2002, and was brought to our hospital on February 1. Neurological examination revealed no apparent worsening of left hemiparesis, left hemisensory disturbance, and left homonymous hemianopsia. CT demonstrated a high density area in the tumor (Fig. 3A). T2*-weighted MR imaging showed a hypointense region within this area indicating hemosiderin (Fig. 3B), which appeared as hyperintense on T1-weighted MR imaging and hypointense and hyperintense on T2-weighted MR imaging suggesting methemoglobin and free methemoglobin, consistent with the components of subacute hemorrhage (Fig. 3C, D). T1-weighted MR imaging revealed a mass lesion including a cystic portion appearing hyperintense to the cerebrospinal fluid and a solid portion with

heterogeneous enhancement after administration of gadolinium-diethylenetriaminepenta-acetic acid (Gd-DTPA) (Fig. 4A–C). Angiography was not performed because of the allergic response to contrast agent containing iodine, although no iodine hypersensitivity had been found at the initial treatment.

Surgical resection of the tumor via the zygomatic approach was performed on May 20, 2002. The tumor was removed piecemeal along the tube of the Ommaya reservoir that had been placed at the initial operation. The cyst content was xanthochromic fluid, suggesting previous hemorrhage. The solid portion of the tumor was reddish, fibrous, and hard. The tumor was well demarcated, and gross total resection was achieved.

Histological examination revealed that the tumor consisted of bipolar astrocytic cells associated with Rosenthal fibers (Fig. 2C), resembling the compact portions of the tumor removed at initial operation in 1987 (Fig. 2B), limited to a small part of the lesion, but mainly degenerative tissue with organizing hematoma (Fig. 2D) and granulation tissue. Ultrastructural examination demonstrated abundant intermediate filaments around the tumor cells (Fig. 5).

CH: cerebellar hemorrhage, ITH: intratumoral hemorrhage.

The diagnosis was recurrent pilocytic astrocytoma with organizing hematoma and granulation tissue. Histological examination revealed no malignant change of the tumor or evidence of angiomia.

There were no intraoperative or postoperative complications. Postoperative MR imaging with Gd-DTPA confirmed gross total resection of the tumor (Fig. 4D). Adjuvant therapy was not performed. The patient was discharged without neurological deterioration in August 2002, and is being followed up with MR imaging at a local clinic without recurrence of the tumor.

Discussion

Symptomatic hemorrhage associated with pilocytic astrocytoma is rare (Tables 1 and 2). High-grade gliomas and metastatic lesions bleed from structural abnormalities of the tumor vessels, tumor invasion of vessel walls, and necrosis. Although the mechanism that results in hemorrhages in pilocytic astrocytomas is unclear, the bleeding may originate from abnormal vessels with thin walls, endothelial proliferation, retiform capillaries, encased aneurysm, stromal degeneration, stretched brain, infarction, coexisting vascular malformations, or congestive vessels. Immediate accumulation of large amounts of blood causing sudden onset of signs or symptoms may be rare but repeated microbleeding resulting in slow and gradual expansion of cysts is common in pilocytic astrocytomas, since regressive alterations in histopathology are observed in these tumors. However, subarachnoid hemorrhage (SAH) associated with pilocytic astrocytoma can cause immedi-
ate headache and vomiting resulting from meningeal stimulation, and disturbance of consciousness from spasm of perforating vessels or compression of brain stem, as well as aneurysmal SAH.\textsuperscript{15,23} Intraventricular or cerebellar hemorrhage can induce acute hydrocephalus, resulting in headache, vomiting, or lethargy.\textsuperscript{13,37}

The tumor was large in our patient, so compensation for the increased intracranial pressure caused by further enlargement of the lesion was probably inadequate, and a slight increase in tumor size might have caused the sudden headache and vomiting. Expansion of the lesion resulting in the symptoms was mainly due to enlargement of the hematoma, because the histological findings revealed that most of the tumor consisted of organizing hematoma and granulation tissue, indicating that bleeding originated from vessels in the granulation tissue. The granulation tissue could have been caused by microbleeding from the astrocytoma, but radiation can also induce formation of granulation tissue and organizing hematoma.\textsuperscript{5,25} Both causes were present in this case. Since association of degenerative change with pilocytic astrocytoma is not uncommon, our diagnosis was recurrent pilocytic astrocytoma with organizing hematoma and granulation tissue, even though proliferation of tumor cells may not have been the primary cause of enlargement of the lesion.\textsuperscript{5}

Eight of the 13 patients with supratentorial pilocytic astrocytoma associated with hemorrhage were adults (Table 1), whereas all seven patients with cerebellar or brain stem pilocytic astrocytoma were under 15 years of age (Table 2). The difference in the age distribution with tumor site may reflect the incidence of the tumors, since no biological differences are evident between pilocytic astrocytomas in juvenile patients and adults, or in the cerebellum and cerebrum.\textsuperscript{5,30} The differential diagnosis of angioma from other mass lesions with repeated bleeding in radiological examinations is thought to be difficult since both appear as mixed density and intensity on CT and MR imaging, respectively.\textsuperscript{28} In addition, the histological findings of pilocytic astrocytoma with hemorrhage are similar to those of angioma.\textsuperscript{5}

Histological examination of almost all of the present lesion found no evidence of angioma but revealed astrocytic tumor cells with organizing hematoma and granulation tissue. Therefore, the histological diagnosis was recurrent pilocytic astrocytoma, although we cannot deny the possibility that angioma had been induced by radiation therapy and then degenerated. Proton MR spectroscopy was not performed in this case. Increased concentration of choline is generally found in primary and secondary brain tumors, and is correlated with the extent of anaplasia.\textsuperscript{11} Lactate can be detected in ischemic lesion, central necrosis or cyst in tumors, and abscess. Increased fatty acid without increase in choline may indicate necrosis.\textsuperscript{13} The decrease in N-acetyl-aspartate is thought to be correlated with the malignancy in glioma.\textsuperscript{20} The peak of choline is absent in cavernous angioma.\textsuperscript{21}

Therefore, MR spectroscopy might have been useful for the differential diagnosis in this case.

Pilocytic astrocytomas are benign tumors that grow slowly, with the exception of pilomyxoid astrocytoma, a more aggressive variant.\textsuperscript{5,6,18,34} Histopathological changes in pilocytic astrocytomas tend toward regressive changes including hyalinization, telangiectatic vessels, necrosis, or lymphocytic infiltration rather than anaplasia, and malignant transformation is rare.\textsuperscript{5} MIB-1 labeling indices range from 0% to 3.9%.\textsuperscript{5} The survival rate of patients with pilocytic astrocytomas is 95.8% at 10 years.\textsuperscript{5} The non-aggressive character of pilocytic astrocytoma indicates a favorable prognosis in most patients after gross total or subtotal resection of the tumor without adjuvant therapy.\textsuperscript{1,4,6,14,30} However, a high incidence of recurrence, ranging from 7% to 48%, has been reported.\textsuperscript{10,29,35} In a series of supratentorial pilocytic astrocytomas, 9% to 20% of cases showed recurrence within 6–12 years.\textsuperscript{1,9,14,30} Since late recurrences of cerebellar pilocytic astrocytoma 36 and 45 years after “complete” surgical resection have been reported, late recurrence could also occur in patients with supratentorial pilocytic astrocytoma.\textsuperscript{5,20}

Three patterns of recurrence can be described: early recurrence, within 4 years of initial surgery, which is more likely to be associated with younger age and diffuse histological appearance; late recurrence, which is unrelated to histological features and the extent of surgery and apparently unpredictable; and late and rare recurrence, caused by malignant histological transformation of the tumor.\textsuperscript{10} Our case can be classified as late recurrence. Three mechanisms of late recurrence have been proposed: true recurrence, which occurs after complete excision of the primary tumor; regrowth of residual tumor after several years of quiescence; and regrowth of residual tumor at an extremely slow rate, in which tumor cells never stop dividing, but cell proliferation is slow, and/or tumor growth is counterbalanced by cell death.\textsuperscript{4} In our case, follow-up CT and MR imaging of the recurrent tumor revealed slow enlargement of the lesion, and the histological study after the second operation revealed that the tumor consisted of both tumor cells
resembling those of primary tumor and degenerative tissue with organizing hematoma and granulation. Therefore, the late recurrence in this case could have been due to slow regrowth of residual tumor with regressive changes.

Postoperative radiotherapy and chemotherapy were performed according to our protocol for gliomas at the time of initial treatment, since tumor resection was subtotal to avoid postoperative neurological deterioration. The efficacy of adjuvant therapy in improving survival rate or inhibiting recurrence has not been substantiated in patients with pilocytic astrocytomas. Adjuvant therapy may be unnecessary in the treatment of pilocytic astrocytomas, since these tumors can be resected or decompressed at recurrence.4 However, long-term follow up is necessary in patients with pilocytic astrocytomas at the time of initial treatment, since tumor recurrence has not been substantiated in patients with pilocytic astrocytomas located in other sites.6,9,14,27 Chemotherapy is effective in patients with pilocytic astrocytomas in the optic pathway and/or hypothalamus or patients younger than 3 years.26,31 However, management of pilocytic astrocytomas generally does not include adjuvant chemotherapy.1,6,14,30

Whether radiotherapy and/or chemotherapy could have been effective in delaying the recurrence in this case remains unknown, but the lesion enlarged in size gradually after these adjuvant therapies. Therefore, long-term follow up is necessary in patients with pilocytic astrocytomas with or without adjuvant therapy, especially if the tumor was not totally removed or a cystic portion was present.
