Abstract

Late onset cerebrospinal fluid (CSF) leakage, such as rhinorrhea or otorrhea, is a rare complication of closed head injury. We encountered two cases of delayed CSF leakage more than 10 years after head injury. In both cases, surgical treatments were performed using intradural approaches, and the dural defects were closed with viable pedicled flaps. After surgery, the CSF leakage was completely cured and no remarkable complication was observed in either case. The present two cases of late onset CSF leakage suggest that surgical repair procedures should be performed as soon as the leaks are discovered. A bifrontal intracranial approach is recommended to treat frontal cranial base leakage. Temporal craniotomy is recommended to treat temporal base leakage. All cases should be treated using an intradural approach, and the dural defect is best repaired with viable pedicled flaps.

Key words: late onset cerebrospinal fluid leakage, delayed rhinorrhea, delayed otorrhea, pedicled flap, intradural approach

Introduction

Cerebrospinal fluid (CSF) leakage, such as rhinorrhea or otorrhea, is a known complication which increases the risk of bacterial meningitis after head injury. Late-onset CSF leakage is a rare complication after closed head injury. More than 90% of cases occur within 3 months after the head injury, whereas cases that present after several years are quite rare. Late-onset CSF otorrhea is especially rare because most otorrhea stops immediately and naturally. Most reports recommend immediate surgical repair for the treatment of delayed CSF leakage, but the optimal surgical approach remains controversial. We describe two cases of delayed CSF leakage treated successfully by surgery.

Case Reports

Case 1: A 66-year-old man was admitted to our department with high fever, headache, and neck stiffness, and was diagnosed with meningitis. More than 20 years previously, he had suffered a severe head injury at work. Neurosurgical operation with craniotomy was undertaken at another hospital. After the operation, there were no complications and no CSF leakage. However, during the past few years, he had noticed serous fluid leakage from his nose. He was diagnosed with bacterial meningitis with CSF rhinorrhea at our hospital. Antibiotic treatment was started immediately. Preoperative computed tomography demonstrated a frontal base bone fracture at the roof of the posterior ethmoidal sinus (Fig. 1). We decided that surgical repair should be undertaken as soon as possible. Bicoronal skin incision and craniotomy with an intradural approach were employed. Under the microscope, we observed a torn and extended bone fracture extending for-
ward to the posterior ethmoidal sinus (Fig. 2). The area lacking dura mater was covered by fragile connective tissue. The dural defect was repaired with a viable pedicled flap made from galea aponeurotica periosteum, which was prepared during the craniotomy (Fig. 3). There was no evidence of CSF leakage soon after surgery and the patient recovered completely.

Case 2: A 61-year-old woman had suffered a head injury in a traffic accident 10 years before visiting our clinic. After the accident, she was treated surgically by craniotomy at another hospital. There were no complications after the surgery. However, during the past few years, she had noticed serous fluid leakage from her left ear and nose without meningitis. A few days before admission to our hospital, she was diagnosed with CSF leakage by an otolaryngologist at another hospital. CSF leakage from a fracture at the upper pyramidal bone was suspected based on radiographic examination (Fig. 4). We decided on surgical treatment for repairing the CSF otorrhea. A left middle fossa approach with a left temporal craniotomy was used. The pyramidal bone was fractured with the dural tear, which was covered with fragile connective tissue (Fig. 5). The dural defect was patched with a viable pedicled (vascularized) temporoparietal fascial flap (Fig. 6).

After the operation, the CSF otorrhea was completely cured without any complications.

Discussion

Leakage of CSF occurs in 2% of all head injuries and 12–30% of all skull base fractures. The frequency of different types of CSF leakage, such as rhinorrhea or otorrhea, was not defined in previous reports. A total of 27 cases of CSF leakage occurred among 1036 cases of closed head injury. In this report, 85% of the 27 cases were CSF rhinorrhea, and 11% were CSF otorrhea. Furthermore, 51 patients had CSF leakage that occurred 24 hours or more after injury, of which 43% were rhinorrhea and 33% were otorrhea. CSF leakage usually occurs within 48 hours after injury and only 5% of cases show delayed onset of CSF leakage, which occurs more than 3 months after head injury. Thus, CSF leakage appearing more than 10 years after closed head trauma is quite rare. Many reports have shown that acute onset traumatic CSF leakage occurs immediately after bone fracture with dural tears, or after remission of the acute inflammation several days later.

The generally accepted explanation for delayed leakage is that the dural defect becomes plugged with brain tissue, as occurred in the present case, or granulation tissue, or that sinus mucosa seals off the CSF leakage but does not provide a barrier against the spread of infection. This interposed tissue then prevents natural dural repair, so a subsequent, often inconsequential, event then disrupts the temporary seal resulting in rhinorrhea. The trigger of late onset CSF leakage is considered to be meningitis, movement, or strong sneezing.

Only 13 reported cases of CSF leakage have appeared more than 10 years after closed head injury, including our two cases. A summary of these 13 cases is shown in Table 1. The mean interval between the trauma and the occurrence of leakage was 19.9 years, with a range of 5 to 35 years. Ten of the 13 cases were complicated with meningitis. At the time of the head injury, nine cases received conservative treatment. However, only our two cases underwent surgery to treat the head injury. Only two cases of late onset CSF otorrhea have been reported. This sug-

gests that spontaneous closure occurs in the majority of patients with traumatic otorrhea, in contrast to rhinorhea.

To repair the dural defect, an intradural approach was used in five cases and an extradural approach in one case. Nonpedicled fascia was used in many cases to repair the dural defect. Late onset CSF leakage should be treated by surgical repair as soon as possible if the leakage does not stop after conservative treatment for several weeks and meningitis cannot be adequately managed. To repair CSF leaks, an intracranial and/or extracranial approach can be chosen, particularly for CSF fistulae resulting from circumscribed fractures of the medial portion of the anterior cranial base, which can be approached via an extracranial rhinosurgical route with good results. Conversely, large cranial base fractures necessitate surgical treatment via a bifrontal intracranial approach, because they are almost always associated with extensive dural tears and cerebral injury.

The dural defect can be closed with pericranium, fascia lata, or temporalis fascia and fibrin glue as a sealant. Viable pedicled flaps, such as the epicranium, as used in our series, have great advantages over free grafts. Pedicled flaps are resistant to infection and are integrated more rapidly than free flaps into the recipient site, providing immediate watertight closure, as has been well documented. We propose that bilateral craniotomy is better, immediately watertight closure, as has been well documented, rapidly than free flaps into the recipient site, providing
