Abstract

A 39-year-old male presented with a spinal neurinoma originating from the T-1 anterior root and located ventral to the spinal cord. The tumor was removed by hemilaminectomy with only partial facetectomy without costotransversectomy. No stabilization was necessary, and no complications secondary to surgery occurred. Costotransversectomy is not necessary for neurinoma ventral to the spinal cord within the spinal canal at T-1 level because the transverse process protrudes more laterally and the spinal canal of the T-1 vertebra is wider than at other thoracic levels.

Key words: posterolateral approach, spinal neurinoma, anterior root, surgery

Received December 14, 1998; Accepted May 20, 1999

Introduction

Spinal neurinomas originating from the anterior roots account for less than 5% of all spinal neurinomas. As the origins of these neurinomas are located on the ventral spinal cord and within the spinal canal without enlargement of the neuroforamen, it is difficult to decide on a surgical approach. Various approaches to lesions at the thoracic levels include the anterior thoracic, posterior, posterolateral, and lateral extrapleural approaches. The anterior approach provides direct access to the ventral surface of the spinal cord. However, the operative procedure is complex and difficult because of the deep, narrow corridor and necessity for vertebrectomy. Moreover, there are potentially formidable sequelae, such as cerebrospinal fluid leakage and respiratory dysfunction. Recently, posterolateral approaches with costotransversectomy have frequently been used for lesions ventral to the spinal cord. The posterolateral approach with dentate ligament section and spinal cord rotation provides excellent exposure to the lateral surface of the spinal cord, but most posterolateral approaches at the thoracic levels require transverse incision of the paraspinal muscles and costotransversectomy.

We present a case of a spinal neurinoma originating from the T-1 anterior root and located ventral to the spinal cord which was treated by hemilaminectomy with only partial facetectomy, and discuss whether costotransversectomy is indispensable at the T-1 level using the posterolateral approach to lesions ventral to the spinal cord.

Case Report

A 39-year-old male had suffered from chest oppression, and numbness and motor weakness of the lower extremities on both sides for about 2 years before admission. His condition had gradually deteriorated. He had a history of drug abuse since the age of 18 years. The patient was transferred to a local hospital when he was unable to walk alone and suffered from confusion due to withdrawal symptoms. The diagnosis was a spinal tumor at the T-1

level. The patient was referred to our hospital for management of the lesion.

Neurological examination demonstrated grossly complete anesthesia of lower than T-3 dermatome, severe disturbance of deep sensation of the lower extremities, and moderate paraparesis. Bladder-bowel functions were grossly normal.

Radiography showed no abnormalities. Magnetic resonance (MR) imaging demonstrated a 2 cm intradural extramedullary mass severely compressing the left spinal cord dorsally at the T-1 level (star). Repeat MR imaging revealed a slight change in tumor location, which indicated mobilization of the tumor in the spinal canal (Fig. 1). Computed tomography (CT) after myelography revealed a thin rim of contrast medium surrounding the margin of the tumor located ventral and right of the spinal cord, which suggested neurinoma rather than meningioma (Fig. 2).

The patient underwent total removal of the tumor in the right-side up, three-quarter position under general anesthesia. Following the longitudinal midline skin incision, the paraspinal muscles on the right were dissected subperiosteally from the spinous process to the T-1 transverse process. T-1 hemilaminectomy with skeletonization of the partial C-7 and T-2 hemilaminae was performed. The base of the spinous process was skeletonized obliquely to obtain space for dorsal rotation of the spinal cord. The T-1 pedicle and parts of the C7-T1 and T1-2 facets were skeletonized to provide direct access to the lateral surface of the spinal cord and to allow T-1 root mobilization (Fig. 3). The tumor originated from the T-1 anterior root, which was located in the epiarachnoid space, and was completely removed.
with no forced retraction of the spinal cord. Neither internal nor external stabilization was used. The histological diagnosis was neurinoma.

The preoperative symptoms and signs subsided completely, except for very slight motor weakness of the left lower extremity and chest oppression one month after surgery. No complications secondary to surgery, such as root signs of T-1, instability, or CSF leakage, occurred.

**Discussion**

The present case of ventrally located spinal neurinoma at the T-1 level could be safely removed by the posterolateral approach without requiring potentially risky procedures to provide direct access to the ventrolateral surface of the spinal cord.

We would like to emphasize two points that made costotransversectomy unnecessary. Firstly, the tumor was identified as a neurinoma preoperatively by CT myelography and serial MR imaging. Therefore, it was unnecessary to treat the ventral site dura mater. Secondly, the T-1 vertebra has morphological characteristics that are different from those of other thoracic vertebrae. The transverse process protrudes more laterally and the spinal canal is wider at the T-1 level than those of other thoracic vertebrae. Therefore, costotransversectomy at the T-1 level is not necessary to obtain direct access to the ventrolateral surface of the spinal cord, although indispensable at the levels of other thoracic vertebrae, as seen by comparing Figs. 2 and 4.

In our case, skeletonization of a limited bone area, including the hemilamina, and the medial half of the facets and the pedicle, allowed considerable mobilization of the affected root, and sectioning of the dentate ligament enabled safe dorsal rotation of the spinal cord. Thereafter, direct access to the ventrolateral surface of the spinal cord was obtained using limited procedures without costotransversectomy. Internal and external stabilization was unnecessary because of the limited area of bone removal. Moreover, the omission of costotransversectomy reduces the degree of paraspinal muscle transection necessary. In our case, paraspinal muscle transection was not required because the muscle mass did not interfere with access to the lateral surface of the spinal cord. Therefore, potential complications caused by paraspinal muscle transection were avoided.

The posterolateral approach without costotransversectomy can be used for neurinoma ventral to the spinal cord within the spinal canal at the T-1 level because of the morphological characteristics of the T-1 vertebra. Consequent limitation of bone removal prevents various complications.
