Methanofullerenes, a class of C₆₀ derivatives, act as negative type e-beam resists with 10-nm resolution and high dry-etch durability. Their sensitivity is \( \sim 10^{-3} \) C/cm², one order of magnitude better than that of C₆₀. We studied sensitivities of methanofullerene resists by systematically changing side chains and have found that the methano bridge and \( >\text{C}=\text{O} \) in the side chains are important in the sensitivity improvement. We realized further sensitivity improvement by synthesizing methanofullerene with 4-6 side chains. This has about two orders of magnitude higher sensitivity \( (3.8\times10^{-4} \) C/cm²) than that of C₆₀.

Keywords: fullerene, methanofullerene, C₆₀, electron beam resist, nanolithography

1. Introduction

We discovered that electron beam (e-beam) irradiation reduces the dissolution rate of C₆₀ films in organic solvents such as monochlorobenzene (MCB), and that it can be used as a high resolution negative e-beam resist with high dry-etch durability [1,2]. However C₆₀ has some drawbacks for use as an e-beam resist. First, C₆₀ films cannot be prepared by spin-coating because of the low viscosity of the C₆₀ solutions. Second, the sensitivity of C₆₀ resist is \( \sim 0.01 \) C/cm², which is 2-3 orders of magnitude lower than that of poly(methylmethacrylate) (PMMA) although it is better than that of inorganic resists [3,4].

To solve these problems, we adopted C₆₀ derivatives, methanofullerene, as e-beam resists [5,6]. Addition of side chains to a C₆₀ cage enhanced the solubility in organic solvents and the viscosity of its solution, which enabled spin-coating to prepare the uniform films.

The methanofullerenes actually acted as a negative type e-beam resist with high resolution and high dry-etch durability. Their sensitivities were \( \sim 10^{-2} \) C/cm², about one order of magnitude higher than that of C₆₀. They are, however, still one order of magnitude lower than that of PMMA.

In this paper, we investigate factors influencing the sensitivity to develop new methanofullerene resists with higher sensitivity.

2. Sensitivity improvement of methanofullerene resists
Figure 1 shows a generalized schematic of the methanofullerene with one addend. A carbon atom is added to the fullerene cage to form a methano bridge (three membered carbon ring).

We investigated three kinds of methanofullerenes with different atoms at the end of side chains, S, Cl, and I, which are labeled as MTF-Ts, MTF-Cl, and MTF-I, respectively (Fig.2). A scattering cross section of an atom against e-beam depends on the atomic weight: a heavier atom generally has a larger cross section. Thus, it is expected that MTF-I has a highest sensitivity because I is the heaviest among the three.

To measure the response of the methanofullerene films to e-beam irradiation, about 300-nm thick films of MTF-Ts, MTF-Cl, and MTF-I were exposed to 20 keV e-beam using a Hitachi S4500 scanning electron microscope (SEM). Then the samples were immersed in MCB for 1 min and rinsed in isopropyl alcohol (IPA) for 10 s and the remaining film thickness was measured by a surface profiler (Dektak3 ST, Sloan).

Figure 3 shows responses of the methanofullerene films to e-beam, where the film thicknesses after developed in MCB for 1 min are plotted as a function of the electron dose. Although the unexposed area of the film was thoroughly solved in MCB within 10 s, the methanofullerene films became insoluble with the dose higher than $\sim 2 \times 10^{-3}$ C/cm$^2$. The sensitivities of the methanofullerenes, defined as the mean value of the two turning points on the graph, are $2.0 \times 10^3$ C/cm$^2$ for MTF-Ts, $2.5 \times 10^3$ C/cm$^2$ for MTF-Cl and $2.3 \times 10^3$ C/cm$^2$ for MTF-I. These are one order of magnitude better than that of C$_{60}$ resist (0.02 C/cm$^2$). Among the three methanofullerene films, the sensitivity difference is very small. This means that the atoms at chain-ends have only a weak effect on the sensitivity.

In our previous letters [7,8], we investigated resist sensitivities of methanofullerenes by systematically changing the length of side chain, and showed that the sensitivity was also only weakly dependent on the chain length. These results suggest that the sensitivity enhancement in methanofullerenes is caused mainly by the structures near the connection sites between the C$_{60}$ cage and the side chain.

There are two characteristic structures in all the methanofullerenes utilized in our experiments: methano bridge and $\text{C}=$O near the connection sites. To assess the effects of these structures we measured sensitivities of a Diels-Alder derivative of C$_{60}$ (DA) and a methanofullerene (MTF11) shown in the Fig.4. MTF11 does not have $\text{C}=$O in the side chain, and
DA does not have either a methano bridge nor an oxygen atom.

The DA and MTF-11 films were exposed to 20 kV e-beams and developed in MCB for one minute. The remaining thicknesses of DA and MTF11 are plotted in Fig.5. Those of C_{60} and MTF-Ts are also plotted for comparison. The sensitivity of DA is \(0.01\text{C/cm}^2\), which is almost the same as that of C_{60}. This indicates the presence of the methano bridge plays an important role in the sensitivity improvement.

The sensitivity of MTF11 is about \(6.4 \times 10^{-3}\text{C/cm}^2\), which is between C_{60} and the methanofullerenes with \(>\text{C}=\text{O}\). The fact that the MTF without \(>\text{C}=\text{O}\) has the lower sensitivity indicates that the oxygen atoms near the cage also contribute to the sensitivity improvement. Oxygen has high electronegativity, which may cause inhomogeneous charge distribution in the C_{60} cage. Thus, the addition of oxygen atom near the cage may make C_{60} more vulnerable to e-beam.

From the above results, we can obtain a guideline to design a higher sensitivity resist: methanofullerene having more side chains with \(>\text{C}=\text{O}\) near the connection sites. Thus, we synthesized a multi-adduct methanofullerene, MTF13. We used a mixture of tetra, penta, and hexa

3. Performance of the methanofullerene resists

To demonstrate performance of the methanofullerene resists, nanometer scale patterns were defined in MTF12 (Fig.7) using the SEM equipped with a pattern generator (Crestec, CPG1000). Figure 7 shows SEM pictures of the defined dots and lines. The diameter of the dots was 10 nm and the line width was 10 nm. In this experiment, the minimum pattern size is not limited by the resist resolution, but by the performance of the exposure system.

Next we compare resist properties (resolution, sensitivity, and dry-etch durability) of the methanofullerenes (MTF-Cl and MTF13) with other e-beam resists: PMMA, polystyrene, a novolac based e-beam resist (SAL 601, Shipley), and C_{60}.

Dry-etch durability was estimated by the etch rate ratio of Si to the resists using reactive ion etching (L-201D-L, ANELVA). The etching conditions were as follows. The etching gas was mixture of SF_6 and CF_4 with flow rate of 12.5 sccm for each and the total pressure was 0.5 Pa. The incident rf power was 18 W. Before the etching, the resist films were exposed to e-beam.

The properties of the resists are summarized in Table I. PMMA has higher sensitivity and 10-nm scale resolution, but the dry-etch durability is weak. SAL601 has good dry-etch durability and high sensitivity, but the resolution is not so high. Compared with other resists, the methanofullerene resists are good e-beam resists capable of high resolution, high dry-etch durability and good sensitivity.

4. Summary

The methanofullerene resists act as negative type e-beam resists with high resolution and high dry-etch durability. Their higher sensitivity than that of C_{60} results from the presence of the methano bridge and >C=O. We realized further two orders of higher sensitivity than that of C_{60} by synthesizing methanofullerene with 4-6 addends.
