Hot Cracking Phenomena in Electron-beam-melted Surface Region of Co-Cr-Mo Alloy*

Shigeki Kakiuchi**, Shogo Tomida**, Hideki Yamagishi**, Takashi Yoneda*** and Kazuhiro Nakata****

The cause of hot cracking in Co-Cr-Mo (CCM) alloy induced by surface melting by electron beam (EB) irradiation was investigated for different EB currents. A regular pattern of linear grooves and ridges was formed by horizontal EB scanning with a square raster pattern. However, some irregular-shaped grooves also occurred. As the EB current was increased, these irregular grooves became larger and cracks appeared within them. Cross-sectional observations showed that the cracks occurred mainly in the heat-affected zone (HAZ) along grain boundaries and extended into the fused zone (FZ). The HAZ cracks terminated at grain boundary precipitates. The fractured surface of the cracks exhibited well-developed cellular-dendritic solidification structures in the FZ, indicating that these were solidification cracks. In contrast, the cracks in the HAZ had an immature dendritic structure with a relatively flat surface, typical of liquation cracks. It can be deduced that the cracks were caused by a liquid film remaining at the grain boundaries, and the driving force for crack propagation was shrinkage distortion caused by the fusion-solidification process.

Key Words: Electron beam, Co-Cr-Mo alloy, Hot cracking phenomena, Fractured surface, Grain boundary

1. Introduction

Co-Cr-Mo (CCM) alloys are often used for implant materials due to their good wear resistance. The sliding surfaces of the joints of these alloys are specular surfaces finished by the polishing process. However, CCM alloys are difficult materials to cut and polish. As a result, the use of machine finishing and hand polishing processes during manufacturing becomes too expensive. Therefore, one of the goals of this study was to save cost and reduce the time required for the polishing process.

The authors previously proposed the use of an electron beam (EB) surface-remelting process to improve the surface quality of as-cast CCM alloys. This processing method is highly energy efficient because reflection does not have a large influence, and surface oxidation is small because processing is carried out in a vacuum. However, in this process some cracks occurred in the remelted zone at the specimen surface due to rapid remelting and solidification. The reason for crack generation during this process is not yet clear.

In the present study, the surface of a CCM alloy casting material was remelted with EB irradiation under various conditions, and the resulting cracks were examined to reveal their origin.

2. Experimental procedures

As-cast CCM alloy was used (Size: 30×30×5 mm) in this study. The composition is shown in Table 1. The surface roughness of the test pieces was adjusted to Ra=0.1–0.2 μm by polishing.

An electron beam multi-surface machine (Tada Electric Co., Ltd., e-FM-0.4LB-1 VL-C5050) was used for the EB irradiation experiment. Schematic diagrams of the EB irradiation setup are shown in Fig. 1. A focused short-pulse EB was used to scan the test pieces and remelt their surface (Fig. 1A). A square raster EB irradiation pattern (EB irradiation area: 20×20 mm) was used (Fig. 1B). EB irradiation was performed under an accelerating voltage of 40 kV, a working distance of 200 mm, a dot pitch of 0.02 mm, and a clock frequency of 10 kHz. The exact focus position of the EB was the test piece surface. In this case, the diameter of the EB was approximately 0.2 mm, and its scan speed was 12 m-min⁻¹.

The dot pitch, which is the distance between the centers of each dot-shaped EB irradiation area, was the same in the X and Y directions. The electron beam current was varied from 1 to 5 mA. The pressure inside the vacuum chamber was less than 3 Pa.

After EB irradiation, the remelted surface zone, its cross section, and the fractured surface of the cracks were examined by optical microscopy and scanning electron microscopy (SEM) together with energy-dispersive X-ray spectroscopy (EDS). In addition, CCM alloy structures were prepared by polishing and etching at 6 V in a solution of methanol (90 ml) and sulfuric acid (10 ml).
3. Results and discussion

Optical and SEM micrographs of the as-cast CCM alloy are shown in Fig. 2. As seen in Fig. 2A, the CCM alloy used in this study had a large grain size. In Figs. 2B and 2C, globular precipitates can be observed between dendrites, and in Fig. 2D, fine precipitates can be seen along the grain boundaries. A large part of precipitates along the grain boundary are not globular precipitates, but fine precipitates in Figs. 2C and 2D.

SEM images and EDS spectra obtained from the as-cast CCM alloy are shown in Fig. 3. More Cr and Mo but less Co are seen in the globular precipitate region (Fig. 3B) compared with the matrix (Fig. 3A). In addition, more Cr but less Co is seen in the fine precipitate region (Fig. 3C) within the grain boundary compared with the matrix. It is assumed that both the globular precipitates and the grain boundary precipitates correspond to the ε-phase (Mo-containing Co-Cr intermetallic compound) \(^7\) that was crystallized by segregation of the solute elements when the cooling rate was low. Mo may have dissolved into the grain boundary precipitates.

A ternary phase diagram of the liquidus projection for Co-Cr-Mo system \(^10\) is shown in Fig. 4. The CCM alloy is a eutectic-type alloy, with the eutectic point \(E\) given by \(L \rightleftharpoons (\text{Co (HT)}) + \text{CoCr (LT)} + \text{Co}_7\text{Mo}_6\), where \(L\) represents the liquid phase. This indicates that solidification of the CCM alloy from the liquid phase into Co, CoCr, and Cr\(_7\)Mo\(_6\) is completed at the ternary eutectic point. The temperature of the liquidus line decreases with increasing Cr and Mo content.

had a fine cellular-dendritic solidification structure, which fused zone (FZ) increased from 25 to the EB current was increased from 1 to 3 mA, the width of the area between the fusion boundary (FB) and the crack tip. As 7B, respectively. Here, the heat-affected zone (HAZ) is defined as irradiation with a current of 1 and 3 mA are shown in Figs. 7A and 7B, respectively. The depth of this zone from the surface is solidification cracking in the FZ. The depth of the FZ in Fig. 7B. In the narrow central zone with a width of approximately 20 μm in Fig. 8C, an immature dendritic pattern with a relatively flat surface is observed. This suggests that the fractured surface of the crack is the result of liquation cracking in the HAZ. In the lower zone, a fine dimple pattern can be observed in Fig. 8D. This appeared in the artificially fractured surface of the BM that was made for SEM observation of the crack surface as a result of being subject to bending stress. Therefore, the liquation cracks did not in fact form in this region. Based on these results, it can be assumed that the cracks were caused by a liquid film remaining at the grain boundaries in both the FZ and the HAZ.

Cross-sectional SEM micrographs of the CCM alloy after EB irradiation with a current of 1 and 3 mA are shown in Figs. 7A and 7B, respectively. Here, the heat-affected zone (HAZ) is defined as an area between the fusion boundary (FB) and the crack tip. As the EB current was increased from 1 to 3 mA, the width of the fused zone (FZ) increased from 25 to 82 μm. In both cases, the FZ had a fine cellular-dendritic solidification structure, which indicated that the solidification rate after remelting was extremely high. As seen in Fig. 7A, at an EB current of 1 mA, a crack occurred at a grain boundary in the HAZ below the FZ. This crack terminated at the FB of the FZ. However, at 3 mA, cracks occurred not only at grain boundaries in the HAZ, but also in the FZ. Some of the HAZ cracks terminated at the FB, but other large cracks extended into the FZ and reached the surface. The width of the crack generation region in the HAZ increased with increasing EB current in a similar manner to that in the FZ. The morphology of the cracks in the HAZ and FZ suggests that cracks are generated in the HAZ along grain boundaries in the base metal (BM).

SEM micrographs of the fractured surface of a crack are shown in Fig. 8 for an EB current of 3 mA. Figs. 8B, 8C, and 8D show higher-magnification SEM micrographs of the three regions indicated in Fig. 8A, which correspond to solidification cracking in the FZ, liquation cracking in the HAZ, and artificial fracturing in the BM, respectively. In the upper zone near the surface, as shown in Fig. 8B, the fractured surface exhibits a well-developed cellular-dendritic solidification structure, which is typical of solidification cracking in the FZ. The depth of this zone from the surface is approximately 70 μm in Fig. 8A, corresponding to the depth of the FZ in Fig. 7B. In the narrow central zone with a width of approximately 20 μm in Fig. 8C, an immature dendritic pattern with a relatively flat surface is observed. This suggests that the fractured surface of the crack is the result of liquation cracking in the HAZ. In the lower zone, a fine dimple pattern can be observed in Fig. 8D. This appeared in the artificially fractured surface of the BM that was made for SEM observation of the crack surface as a result of being subject to bending stress. Therefore, the liquation cracks did not in fact form in this region. Based on these results, it can be assumed that the cracks were caused by a liquid film remaining at the grain boundaries in both the FZ and the HAZ.

Cross-sectional SEM micrographs of the FZ in the CCM alloy are shown at different magnifications in Fig. 9 for an EB current of 3 mA. These images indicate that the cracks extend through the FZ and the HAZ and terminate at fine grain boundary precipitates in the BM. Partial liquation at the grain boundaries may have occurred as a result of these precipitates.
remelted surface region of the as-cast CCM alloy. Crack length and the number of cracks strongly increased in the relation to microstructures. The following results were obtained:

(1) As the EB current was increased from 1 to 2 mA, both the total cross section, and fractured surface of the cracks themselves in the remelted surface region of the as-cast CCM alloy.

(2) The cracks occurred mainly in the HAZ along the grain boundaries, and some extended into the FZ. These HAZ cracks terminated at grain boundary precipitates.

(3) Two types of cracks were observed; these were solidification cracks in the FZ and liquation cracks in the HAZ.

4. Conclusions

The surface of a CCM alloy cast material was remelted by EB irradiation with different EB currents, and an investigation was carried out into hot cracking phenomena on the remelted surface, cross section, and fractured surface of the cracks themselves in relation to microstructures. The following results were obtained:

(1) As the EB current was increased from 1 to 2 mA, both the total crack length and the number of cracks strongly increased in the remelted surface region of the as-cast CCM alloy.
