Warthin’s tumor (WT), also known as adenolymphoma, papillary cystadenoma, cystadenolymphoma, and epitheliolymphoid cyst, is a common benign tumor of the parotid glands which may occur synchronously or metachronously in the same or contralateral gland, so may be associ-
CASE REPORT

A 102-year-old man visited an ear, nose, and throat clinic in January 2005 because of a mass in the left side of the neck persisting for 1 month. The mass was painless and non-tender, but had been increasing in size gradually. His history was unremarkable, except for hypertension and prostatomegaly. Physical examination revealed a tumor approximately 3 cm below the left angle of the mandible. The mass was 2-3 cm in diameter, and freely moveable. The patient had no other symptoms and denied weight loss, fever, chills, or night sweats. The remainder of the physical examination and all laboratory test results were within normal limits except for mild anemia.

Ultrasonography showed a well-defined hypoechoic mass with a central hyperechoic lesion, measuring 20 mm × 32 mm × 24 mm (Fig. 1). Ultrasonography-guided fine needle aspiration biopsy of the central lesion indicated class II, or no malignancy. Color Doppler ultrasonography showed relatively rich vascularization, but no other cervical lymphadenopathy.

The tumor was located under the platysma, in the left side of the neck. The mass was easily extirpated and had no communication with the submandibular gland, parotid gland, or skin. The excised tumor was soft and well encapsulated, and the cut surface was grayish-brown. No other

![Fig. 1. Ultrasonography scans on admission. A well-defined hypoechoic mass is shown.](image)
cervical lymphadenopathy was found.

Histological examination revealed a combination of WT and NHL. Postoperative staging examination including chest radiography, bone scan, and computed tomography of the abdomen and pelvis revealed no evidence of dissemination of malignant lymphoma, nodal swelling, or hepatosplenomegaly. Hematological and biochemical investigations showed increased soluble interleukin-2 receptor level (1,060 U/ml; normal value 220-530 U/ml). Other evaluations were almost within normal limits. The Ann Arbor stage was not clear, because the clinical workup was incomplete, and bone marrow aspiration had not been done.

No therapy was initiated on account of the patient’s physical condition and his advanced age. The patient was periodically followed up by ultrasonography. Four months after the diagnosis, he presented with multiple lymphadenopathies in both sides of the neck. The soluble interleukin-2 receptor level was increased (1,450 U/ml).

The patient was treated with combination chemotherapy (CHOP) using cyclophosphamide (300 mg on day 1), adriamycin (30 mg on day 1), vincristine (1.0 mg on day 1), and prednisone (30 mg on days 1 to 5). The dosage was one-third of the normal. Following two cycles of this CHOP chemotherapy, the multiple lymphadenopathies in his neck had regressed almost to normal size. However, whole body debility advanced gradually, and he died 10 months after the initial diagnosis.

Histological examination of the surgical specimen showed the classical composite appearance of WT (Figs. 2-4). The epithelial component

Malignant Lymphoma Arising from Heterotopic Warthin’s Tumor

Consisted of a double layer of tall columnar cells with granular acidophilic cytoplasm which formed regular glandular spaces with broad or fine papillae. The abundant lymphoid stroma was partially replaced by lymphoma cells, and Reed-Sternberg cells were not found.

Immunohistochemical examination of the large neoplastic cells showed positive reaction for CD20, CD79a, and B cell-specific activator protein (paired box gene-5), and negative reaction for CD3, CD5, CD10, CD15, and CD30. The neoplastic cells were diffusely and strongly positive for CD20 (Fig. 5) and negative for CD3. These findings strongly suggest B-cell lineage. The final histological diagnosis was malignant lymphoma, diffuse large B-cell type, arising from heterotopic WT. Clonality study or in situ hybridization may be useful for precise diagnosis. They should be performed in future.

Discussion

Carcinoma arising in a pleomorphic adenoma is well known, but malignant transformation within WT is rare (Nagao et al. 1981). The incidence of WT was 11.5% of all parotid tumors and the incidence of malignant transformation in WT was 1.1% in one series (Nagao et al. 1998). Malignant transformation is rarer in the lymphoid component than the epithelial component to our knowledge. Malignant lymphoma apparently arising in the lymphoid component is extremely rare. Some cases have no remnant of the lymphoid component, which normally occurs in WT, as this was totally replaced by malignant lymphoma in the advanced disease. In our case, the epithelial component was clearly recognizable, showed no significant abnormalities, and the lymphoid component was partially replaced by NHL. Furthermore, the NHL arose from heterotopic WT, so our case is extremely unusual.

Heterotopic salivary gland and neoplasms

Heterotopic salivary gland refers to the presence of salivary tissue at sites other than the three major salivary glands and the minor salivary glands. Heterotopic salivary gland tissue may occur in the lymph nodes, external auditory canal, thyroglossal duct cyst, hypophysis, mandible, mastoid bone, middle ear, tongue, sternocleidomastoid joint, thyroid, parathyroid glands, and in the upper and lower neck regions (Pesavento and Ferlito 1976; Ferlito et al. 1999). Cervical heterotopic salivary tissue or neoplasm may present as a mass, cyst, or sialo-cutaneous fistula (draining sinus). Salivary gland in the cervical lymph node is uncommon, but the incidence of salivary heterotopia in the parotid lymph nodes has been reported as 67.7% (Shinohara et al. 1992), 25% (Seifert and Geiler 1956). On the other hand, the incidence of salivary heterotopia in extraparotid lymph node is rather low at 12.2% (Shinohara et al. 1992).

Condensation of mesenchyma may occur as a later event, and as a result, either lymph nodes are trapped within the parotid gland or salivary gland is included within the paraparotid lymph nodes (Singer et al. 1979). This hypothesis explains the presence of heterotopic salivary tissue in the upper neck and periparotid regions. On the other hand, there may be a relationship to the brachial apparatus, specifically, the cervical sinus of His. Defective closure of the sinus with salivary gland tissue arising from heteroplasia of ectodermal lining of the sinus remnant is a plausible explanation for salivary heterotopia (Youngs and Scofield 1967), and may explain the appear-
ance of salivary tissue in the lower neck. Clearly there is a close relationship between the parotid salivary gland and lymphoid tissue.

Reviews of neoplasms arising from the heterotopic salivary glands found that approximately 60-80% of heterotopic salivary tumors are benign, and mainly occur in adults, with few pediatric cases (Ferlito et al. 1999; Daniel and McGuirt 2005). WT is the most frequent neoplasm, followed by pleomorphic adenoma. On the other hand, mucoepidermoid carcinoma was the most common malignant neoplasm. The most popular hypothesis for the pathogenesis of WT is neoplastic proliferation of heterotopic salivary ducts, which are present in the pre-existing intraparotid or paraparotid lymphoid tissue (Seifert et al. 1980). Heterotopic salivary gland tissue can be localized in the cervical lymph nodes. Except for WT, primary salivary gland tumors rarely develop in the lymph nodes of the parotid gland or the cervical lymph nodes. WT is accepted to occur in 8% of cervical lymph nodes (Snyderman et al. 1986). In a sense, WT may be more a lesion of the lymph nodes than the salivary glands.

**WT and its malignant transformation**

Examples of WT associated with disseminated NHL or Hodgkin’s disease have been reported (Seifert et al. 1980), although first detection of malignant lymphomas in the lymphoid stroma of WT is less common. Most of the 16 reported cases were NHL (Table 1). Malignant transformation occurring in WT is unusual.

In contrast, malignant lymphomas are not rare in patients with primary immune sialadenitis with or without other symptoms of Sjögren’s syndrome. Patients with Sjögren’s syndrome have a high risk of developing malignant lymphoma, 40 times higher than in the normal population, so the lymphoma seems more likely to involve the WT secondarily. Malignant lymphoma arising from the salivary gland accounts for 40% of malignant lymphoma of the head and neck, and 5% of all extranodal lymphoma in such patients. The NHL:

**HD, Hodgkin disease; NHL, non-Hodgkin lymphoma; NA, not available; LN, lymph node.**
Hodgkin’s disease ratio is 85:15 in salivary gland lymphomas (Seifert 1991). The occurrence of malignant tumor in accessory parotid gland is much higher than in the main parotid gland (Johnson and Spiro 1979). Whether heterotopic WT is more likely to transform into malignant lymphoma than WT in the main salivary glands remains unclear, because cases which can be identified as NHL initially arising from WT are extremely rare.

The pathogenesis of the malignant transformation of WT is still unknown, but the effect of radiation exposure on the salivary gland is of special interest. Metaplasia in the epithelial component of WT was found in 7.5% of one series, suggesting a relationship with the past irradiation history (Seifert et al. 1980). A review of the incidence and pathology of malignant and benign salivary gland tumors after high radiation exposure caused by atomic bomb blast included a case of mucoepidermoid carcinoma associated with pre-existing WT (Saku et al. 1997). The relationship of NHL arising from WT to previous radiation therapy has been discussed by several authors. In our case, the patient had no history of radiotherapy, so there may be other unknown factors.

The relationship between WT and interleukin-2 receptor level remains unclear. Reported cases have not shown the values. Our cases of WT have shown various values. However, inflammatory rapid swelling is often seen in patients with WT. Therefore, increased interleukin-2 receptor level is quite possible in such a situation. Further examination will be necessary to clarify this point.

Treatment of heterotopic salivary gland

Malignant transformation of the individual components of WT may be considered rare but not exceptional. The initial appearance of malignant lymphomas is frequently in the lymph nodes of the cervical region. Only four cases of malignant lymphoma have arisen from heterotopic WT in the neck. Such cases are rare and may be mistaken as malignant lymphomas arising from the cervical lymph nodes. The lymphoid stroma of WT is part of the systemic lymphoid tissue, so is likely to be involved in disseminated lymphoma. In the advanced stages, the distinction between primary and secondary lymphomas of the salivary gland may be impossible. Heterotopic salivary tissue in the cervical region is probably more common than previously recognized histologically. Neoplasms arising from heterotopic salivary tissue should be considered in the differential diagnosis for isolated neck masses. Accurate diagnosis can only be established after removal. Even if heterotopic salivary lesion presents with no symptom, early removal with careful and periodic follow up is recommended, especially in long-term progressive or pediatric cases.

Acknowledgments

We wish to thank Dr. Kouichi Nagao for his assistance.
