Bone marrow-derived cells (BMDC) play crucial roles in tissue regeneration. Granulocyte-colony stimulating factor (G-CSF) mobilizes BMDC and may facilitate the repair of kidney tissues after ischemia/reperfusion (I/R) injury. The tissue protective action of resveratrol, an antioxidant, might modify the regenerating potential of BMDC in I/R renal injury. This study examined whether G-CSF and/or resveratrol affect the recruitment of BMDC into vascular endothelial cells and renal tubular cells and the kidney function after I/R injury. I/R renal injury was induced in female mice that had been lethally irradiated and transplanted with male bone marrow cells. The mice were given saline, resveratrol or G-CSF, daily for 7 days. Non-irradiated and non-bone-marrow-transplanted female mice, which underwent the same kidney injury, were included as control. White blood cell (WBC) count and serum creatinine were monitored. Immunohistologic evaluation for renal tubular cells (cytokeratin) and endothelial cells (factor VIII-related antigen), and fluorescence in situ hybridization for mouse Y chromosome were performed. Although WBC was significantly higher in the G-CSF group, there was no significant difference in creatinine levels among all groups. Factor VIII-related antigen-positive cells with a Y-chromosome signal were identified in the capillary wall between renal tubuli and most frequently seen in the G-CSF group ($p < 0.0001$). Resveratrol did not affect kidney recovery in this model. No cytokeratin-positive renal tubular cells having a Y-chromosome signal were identified. In conclusion, BMDC are recruited into endothelial cell in I/R renal injury without apparent renal tubular cell regeneration, and G-CSF facilitates the endothelial cell regeneration.

demonstrated that resveratrol, an antioxidant, had a protective effect on kidney function after I/R injury by attenuating CD86 expression (Saito et al. 2005). The tissue protective action of resveratrol might modify the regenerating potential of BMDC. The aim of the present study was to elucidate whether G-CSF and/or resveratrol affect the recruitment of BMDC into vascular endothelial cells and tubular cells of the kidney and the recovery of kidney function after acute ischemic injury.

**Materials and Methods**

**Bone marrow transplantation**

Five- to six-week-old female recipient mice (BALB/c, CLEA Japan Inc., Tokyo) underwent whole-body X-ray irradiation of 10 Gray in a single dose to ablate their bone marrow. Meanwhile, the same number of male donor mice (BALB/c) was sacrificed by CO₂ inhalation, and bone marrow cells of these mice were extracted from the femur, suspended in RPMI-1640 medium (Gibco BRL, Tokyo), filtered with a pore size of 40 μm (40 μm Cell Strainer, BD Biosciences, San Jose, CA, USA) and re-suspended in RPMI-1640 medium at a concentration of 3.0 × 10⁷/ml. After irradiation, female mice received an injection of male mouse bone marrow of 10⁷ cells through the tail vein.

**Ischemia/reperfusion renal injury**

After 4 weeks, 35 irradiated and bone marrow-transplanted female mice were randomly assigned either to the BMT/C group (9 mice), resveratrol group (13 mice) or G-CSF group (13 mice), and were anesthetized by intraperitoneal pentobarbital injection, and the right kidney of each mouse was removed. Since it has been reported that 30 min of bilateral I/R cause reversible renal ischemic injury without severe lethargy (Kale et al. 2003), we blocked left renal blood flow for 30 min with a vessel clamp (Disposable Clip, Natume Seisakusyo Co., Ltd., Tokyo) and then blood flow was restored. Eight non-irradiated and non-bone-marrow-transplanted female mice (BALB/c) underwent the same surgery.

**Drug administration**

Of 43 female mice that received the surgery, 39 (90.7%) survived. Of the 39 mice, 8 in the control group and 8 in the BMT/C group were given normal saline (0.2 ml, i.p.), 11 were given resveratrol (4 mg/kg prepared in
10% ethanol, i.p.) (Sigma, St. Louis, MO, USA) and 12 G-CSF (100 μg/kg, s.c.) (recombinant human G-CSF, Chugai Pharmaceutical Co. Ltd., Tokyo) from day 1 daily for 7 consecutive days.

**Blood and tissue samples**

Peripheral blood samples were collected from the tail vein, and white blood cells (WBC) were counted on a Burker-Turk glass slide, and serum creatinine levels were measured by Jaffe’s method using a Kyokuto creatinine test (Kyokuto Pharmaceutical Industrial Co., Ltd., Tokyo) according to the manufacturer’s instructions. WBC and serum creatinine levels were monitored on day 0 (preoperatively), 1, 3 and 7 and weekly thereafter for 4 weeks. All mice were then sacrificed, and the kidneys were removed and fixed in 10% buffered formalin for 24 hrs, embedded in paraffin, and used for histological studies.

**Immunohistochemistry**

Five-μm sections were sliced from each paraffin-embedded tissue block and mounted on glass slides. Tissue sections were deparaffinized, dehydrated, digested in 0.4% pepsin for 40 min at 37°C, and rinsed in water. Endogenous peroxidase activity was blocked by incubation in 0.3% H$_2$O$_2$/methanol for 20 min at room temperature, and the tissue sections were rinsed in PBS. A protein blocking agent (Dako Japan Co. Ltd., Tokyo) was applied for 30 min, and the tissue sections were rinsed in PBS.

For demonstration of the factor-VIII related antigen, the primary antibody (rabbit polyclonal anti-factor-VIII-related antigen antibody, Dako Japan Co., Ltd.) was applied on the sections at a dilution of 1/100 for 60 minutes at room temperature. To detect the antigen-antibody reaction, a LSAB2 Biotinylated Link Antibody Rabbit/Mouse TM kit (Dako Japan Co., Ltd.) was used according to the manufacturer’s instructions.

For the demonstration of cytokeratin 18, the primary antibody (CBL 177, Cymbus-Biotechnology Ltd., Hampshire, UK) was applied on sections at a dilution of 1/100 for 60 minutes at room temperature. To detect the antigen-antibody reaction, a ChemMate EnVision Detection Kit/HRP (DAB) Rabbit/Mouse™ kit (Dako Japan Co., Ltd.) was used according to the manufacturer’s instructions.

**Fluorescence in situ hybridization**

A DNA probe for total mouse chromosome Y (Q-Biogene Inc., Carlsbad, CA, USA) was diluted with 2 volumes of hybridization buffer (CEP hybridization buffer™, Vysis Inc., Downers Grove, IL, USA), and an aliquot of the mixture was applied onto a tissue section, which was then covered with a cover slip and shielded with rubber cement. The probe mixture and target DNA were denatured at 80°C for 2 min, annealed at 50°C for 30 min, and then incubated at 37°C overnight in a hands-free denaturation and hybridization system (HYBrite, Vysis Inc.). After hybridization, tissue sections were washed in a solution of 1.5 M urea and 0.1x SCC (pH7.2) at 45°C for 10 min, and this washing was repeated 3 times. Tissue sections were equilibrated in 2x SCC for 5 min at room temperature. Nuclei were then counterstained with 4,6-diamino-2-phenylindole p-phenylenediamine and anti-fade mounting solution (Vysis Inc.). The tissue sections were kept in a black box at 4°C until fluorescence microscopic evaluation.

**Histological identification of tissue regeneration by bone-marrow-derived cells**

To identify the possible regeneration of endothelial cells and tubular epithelial cells by BMDC within the mouse kidney, Y-chromosome in situ hybridization was combined with immunohistochemistry.

Microscopic images of the mouse kidney stained with an antibody for renal tubular cells (cytokeratin 18) or endothelial cells (factor-VIII-related antigen) were captured under a microscope (BX-50, Olympus Corp., Tokyo) equipped with a CCD camera (Nikon, Tokyo) with a magnification of × 200. Fluorescence in situ hybridization with a DNA probe for mouse Y chromosome was then performed on the same slide. The slide was scanned with a magnification of × 400, and an image of the area in which Y-chromosome-positive cells were most frequently observed was captured using a CCD camera (Nikon). Using immunohistochemistry pictures as a reference, the number of immunohistologically positive cells with a Y-chromosome signal was counted.

The results are represented as the mean ± standard deviation. Statistical analyses were performed by Student’s non-paired t-test using StatView 5.0 J software (SAS Institute Japan Ltd., Tokyo), and p-values less than 0.05 were considered significant.

This study was approved by the Institutional Ethical Board of the Akita University School of Medicine.

**Results**

**Mouse body weight**

Postoperatively, the mean body weight of
irradiated mice in the BMT/C, G-CSF and resveratrol groups continuously decreased until day 3 and gradually increased thereafter, while the mean body weight of the non-irradiated control mice did not show any apparent decrease. The mean body weights of the irradiated mice in BMT/C, G-CSF and resveratrol groups were lower than that of non-irradiated and non-bone-marrow-transplanted control mice, but there were no significant differences in mean body weight among BMT/C, G-CSF and resveratrol groups. BMT/C, irradiated and bone-marrow-transplanted control.

\* p < 0.05, \**p < 0.0001; Control vs BMT/C.

**White blood cell count**

WBC was significantly higher in the G-CSF group at mean levels of $27.7 \times 10^3 \pm 10.3 \times 10^3/\mu l$ and $32.8 \times 10^3 \pm 14.6 \times 10^3/\mu l$ on day 3 and day 7, respectively, while there was no significant difference in the mean WBC among the BMT/C, resveratrol and non-irradiated control groups at any time of monitoring (Fig. 2).

\* p < 0.05, \**p < 0.0001; Control vs G-CSF.
Serum creatinine level

Serum creatinine levels reached a peak on day 1 in all groups. There was no significant difference in the peak creatinine level among all groups. On day 28, the mean creatinine level of the G-CSF group (0.96 mg/dl) was not different from that of the control group (0.95 mg/dl, \( p = 0.92 \)), BMT/C group (1.06 mg/dl, \( p = 0.13 \)) and resveratrol group (1.03 mg/dl, \( p = 0.4 \)) (Fig. 3).

Y-chromosome-positive cells

First, a chimerism in BMDC was analyzed in three mice 4 weeks after irradiation and bone marrow transplantation. All bone marrow cells obtained from the femuri of these mice were shown to have one Y-chromosome signal, and were confirmed to be of donor origin (data not shown).

Next, we evaluated the effect of G-CSF and resveratrol on the reconstruction of renal capillaries and tubuli. Factor VIII-related antigen-positive cells with a Y-chromosome signal were clearly identified on the luminal side of the capillary wall between renal tubuli (Fig. 4A). Most of these cells were observed in the boundary between the cortex and medulla, but some were also found in the medulla. The morphologic appearances of these cells were compatible with those of capillary endothelial cells. The mean number of those cells was 0.0 ± 0.0, 2.71 ± 1.25, 3.71 ± 1.50 and 10.2 ± 1.33 in the middle power field (×400) in non-irradiated control, BMT/C, resveratrol and G-CSF groups, respectively, and was highest in the G-CSF group (\( p < 0.0001 \)) (Fig. 5). Occasionally we found cellular nuclei positive for a Y chromosome in the renal tubuli, and careful microscopic observation revealed these nuclei to be infiltrated or superimposed nuclei of non-tubular-epithelial cells. No cytokeratin18-positive renal tubular cells having a Y-chromosome signal were identified in any mice in this study (Fig. 4B).

DISCUSSION

Similar to a study by Crosby et al. (2000) that showed hematopoietic stem cell transformation into adult blood vessels in the heart, we found that BMDC were mobilized to the kidney after I/R injury and transformed into endothelial cells. These endothelial cells were most frequently identified in the boundary between the cortex and medulla, where I/R injury has been shown to occur most severely (Kale et al. 2003). This finding suggests that BMDC are recruited to the injured area of the kidney and play a role in repairing the injury. Since we did not evaluate leucocyte markers on endothelial cells, our finding does not exclude possible fusion between
BMDC and endothelial cells as a mechanism of endothelial transformation, which has been suggested by Reinders et al. (2006). In a recent review, Young et al. (2007) suggested that endothelial progenitor cells, a fraction of BMDC, can proliferate and differentiate into endothelial cells in vitro. Further studies are required to elucidate whether these progenitor cells maintain proliferating ability in renal tissue damaged by I/R injury.

In this study, G-CSF seemed to facilitate the transformation of BMDC into endothelial cells in the kidney after I/R injury. The number of endothelial cells judged to be transformed from BMDC by G-CSF was 3.7 or 2.7 times as high as that by saline administration or resveratrol, respectively. We did not count the number of BMDC in peripheral circulation that were mobilized from bone marrow by the administration of G-CSF. Classic BMDC are characterized by surface markers as Lin-Sca-1 + c-Kit + cells, and

Fig. 4. Immunohistochemistry and fluorescence in situ hybridization of mouse kidneys 4 weeks after induction of renal ischemia/reperfusion injury. Factor VIII-related antigen-positive cells with a Y-chromosome signal were clearly identified in the capillary wall between renal tubuli (Fig. 4A). Arrows (▽) indicate the same nuclei. Upper row: boundary between cortex and medulla. Lower row: medulla. Factor VIII-related antigen (original magnification × 200), DAPI and Y-chromosome (magnification × 1,000).

However, no cytokeratin-positive renal tubular cell having a Y-chromosome signal was identified (Fig. 4B). Arrows (▽) indicate the same nucleus of non-renal-tubular interstitial cells with a Y-chromosome but negative for cytokeratin 18. Cytokeratin 18, DAPI and Y-chromosome (magnification × 1,000). DAPI, 4,6-diamino-2-phenylindole p-phenylenediamine
these cells represent only 0.01% of BMDC that are not found in detectable numbers in the peripheral circulation under normal conditions (Kale et al. 2003). G-CSF and stem cell factor are suggested to mobilize BMDC at 250 times as high as the baseline level (Körbling and Estrov 2003). These BMDC contribute to the repopulation of the injured vascular endothelium and could indirectly affect renal tubular regeneration (Duffield et al. 2005; Reinders et al. 2006), and may facilitate early recovery from I/R renal injury.

Renal function recovery by G-CSF, however, was unremarkable in our study. Tögel et al. (2004) reported that BMDC mobilization via G-CSF had severe adverse effects on renal function after preconditioning with G-CSF; however, we gave G-CSF after inducing I/R injury, and no deterioration of renal function was found by G-CSF administration. The effect of G-CSF on the kidney during renal injury remains controversial and may, at least in part, depend on the time frame of G-CSF action (Nishida and Hamaoka 2006). Recent studies have elucidated the recovery mechanism after kidney injury (Rafii and Lyden 2003; Reinders et al. 2006; Young et al. 2007). Leucocytes and platelets in damaged renal tissue deliver angiogenesis factors, such as VEGF and SDF-1, into the local site. Endogenous G-CSF is also produced mainly by macrophages. These factors mediate the proliferation of local endothelial cells, and/or facilitate the recruitment of BMDC. If BMDC mobilized by the administration of G-CSF induces the majority repopulation of injured vascular endothelium, G-CSF might facilitate the recovery of renal function; however, our study was unable to find a substantial improving effect of G-CSF on the recovery of renal function as evaluated by the serum creatinine level. These endogenous angiogenesis factors may dominate exogenous G-CSF in capillary endothelial recovery in I/R injury, and thus G-CSF and BMDC made only a small contribution to repopulation of the injured vascular endothelium in our study model.

In our study, we failed to demonstrate renal tubular regeneration by BMDC. A review of recent studies which had claimed renal tubular regeneration by BMDC revealed that serum creat-
injure post-I/R increased to 3.6 to 17.0 times as high as that of pre-I/R (Ysebaert et al. 2000; Brodsky et al. 2002; Duffield et al. 2005; Iwasaki et al. 2005). Broekema et al. (2005) reported that the severity of renal damage is associated with the extent of tubular epithelial regeneration by BMDC after I/R injury. Renal damage with a substantial but modest increase of serum creatinine in our study may thus have hampered the identification of tubular epithelial regeneration by BMDC. Recently, however, by deconvolution microscopic analysis, Duffield et al. (2005) suggested that tubular epithelial regeneration by BMDC was likely artifacts caused by the staining technique or the superimposition of a tubular cell and an infiltrating BMDC. Xenotransplantation of human hematopoietic stem cells into immunodeficient mouse kidneys after I/R injury demonstrated that these cells did not readily acquire a renal tubular cell phenotype and were restricted to hematopoietic lineage and, to a limited extent, endothelial lineages (Dekel et al. 2006). Thus, it remains to be clarified whether the cell source of tubular repair is the proliferation of endogenous renal cells or/and BMDC (Krause and Cantley 2005).

By investigating the restoration of endothelial cells and renal tubular cells, our study revealed that BMDC are recruited into endothelial cell in I/R renal injury without apparent renal tubular cell regeneration. To our knowledge, this is the first report to demonstrate that endothelial cell regeneration occurs in mild I/R renal injury in which renal tubular regeneration by BMDC has not taken place. In addition, this may fit the recent finding that endothelial damage preceded renal tubular damage in I/R injury and acute renal failure (Kakoki et al. 2000; Brodsky et al. 2002).

Resveratrol has been shown to restore kidney function in I/R injury in animal experiments (Giovannini et al. 2001; Saito et al. 2005), although our study on mice failed to demonstrate a protective effect. Giovannini et al. (2001) blocked rat renal arteries for 40 minutes and administered resveratrol at 0.23 μg/kg, while Saito et al. (2005) blocked rat renal arteries for 60 min and administered resveratrol at 4 mg/kg. They both found decreased serum creatinine levels by resveratrol compared with the vehicle. These findings suggest that experimental conditions might explain the discrepancy between our findings and previous reports. Further studies are necessary to elucidate whether the resveratrol modifies the regenerating potential of BMDC by its tissue protective action.

In conclusion, our results confirm that BMDC are recruited into vascular endothelial cells of the kidney after I/R injury, while the regeneration of renal tubular cells originating from BMDC could not be demonstrated. Furthermore, the administration of G-CSF may facilitate the recruitment of bone marrow-derived endothelial cells while its contribution to kidney function recovery was not significant. In addition, resveratrol, an antioxidant, did not affect the recovery of kidney function in this model.
