Eosinophils contribute to the pathophysiology of allergic and infectious diseases, albeit their molecular functions remain unknown. Mature eosinophils are identified by their unique morphology and staining characteristics. However, it is difficult to fractionate living eosinophils by flow cytometry because these granulocytes express multiple cell surface markers that are shared by other cells of hematopoietic or non-hematopoietic origin. In this study, we describe a flow cytometry-based method to enumerate and fractionate eosinophils by developmental stages. To fractionate these cell types, we used transgenic mouse lines that express fluorescent proteins under control of the Gata1 gene hematopoietic regulatory region (Gata1-HRD), which is exclusively active in Gata1-expressing hematopoietic cells, including eosinophils. As expected, mature eosinophils were highly enriched in the fluorescent reporter-expressing subfraction of bone marrow myeloid cells that were negatively selected by using multiple antibodies against B220, CD4, CD8, Ter119, c-Kit and CD71. Cytochemical analyses of flow-sorted cells identified the cells in this fraction as eosinophils harboring eosinophilic granules. Additionally, expression of eosinophil-specific genes, for instance eosinophil enzymes and the IL-5 receptor alpha gene, were specifically detected in this fraction. The expression of these eosinophil-specific genes increased as the cells differentiated. This method for enrichment of bone marrow eosinophils is applicable to fractionation of eosinophils and bronchoalveolar lavage fluid from transgenic mice with atopic asthma. Thus, both pathological and developmental stages of eosinophils are efficiently fractionated by this flow cytometry-based method using Gata1-HRD transgenic reporter mice. This study, therefore, proposes a useful means to study the experimental allergic and inflammatory systems.

Keywords: Eosinophils/GATA1/GATA2/transgenic mice/flow cytometry

Eosinophils are multifunctional granulocytes implicated in diverse immune responses, which include parasitic infections and allergic disease. Eosinophils normally constitute only 1–3% of peripheral blood cells, but upon diverse stimuli, are increased in number and recruited to sites of inflammation (Humbles et al. 2004; Lee et al. 2004; Rothenberg and Hogan 2006). Eosinophils secrete a variety of granule-associated pro-inflammatory cytotoxic proteins, including major basic protein (MBP) and eosinophil peroxidase (EPX), which contribute to airway damage and alterations in airway structure (reviewed in Rothenberg and Hogan 2006).

Allergic disease of the respiratory tract is characterized by the increased infiltration of eosinophils into the associated tissues (Rothenberg and Hogan 2006). Detection and quantification of eosinophils in fluids, such as bronchoalveolar lavage fluid (BALF) or lung tissue are standard procedures in murine models of allergic disease and viral infection. For example, when mice are challenged with aerosolized chicken ovalbumin (OVA), the eosinophil population increases in an interleukin (IL)-5-dependent manner in the bone marrow, peripheral blood and in the BALF (Foster et al. 1996; Kopf et al. 1996). Detection of eosinophils has primarily been based on morphologic criteria, i.e., granulocytes with prominent eosinophil-specific basic granules (Shen et al. 2003; Ishizaki et al. 2006; Stevens et al. 2007). This morphologic identification approach has several disadvantages, including variability in staining procedures, uniformity of inflammatory cell distribution, and reliance on the subjective interpretation of cell morphology in...
the quantitation of infiltrating cells.

To investigate molecular events in disease influenced by the eosinophil population, fractionation of living eosinophils is necessary. To date, specific types of monoclonal antibodies combined with strict forward/side scatter gating are used in flow cytometry-based methods to fractionate the cells (Hansel et al. 1991; Du et al. 2002; Iwasaki et al. 2005; Ishizaki et al. 2006; Munoz and Leff 2006; Stevens et al. 2007; Fukushima et al. 2009; Mori et al. 2009; Shen et al. 2009). However, expression of multiple cell surface markers (e.g. CD16, Gr1, Mac1, etc.) that are shared by other cells of hematopoietic origin and are normally present in inflammatory infiltrates, hampers the easy detection of eosinophils using flow cytometry (Hansel et al. 1991; Gounni et al. 2000; Stevens et al. 2007; Fukushima et al. 2009). To analyze the physiology and pathology of eosinophils, cytokine-induced differentiation systems of hematopoietic progenitor cells or cell lines are exploited (Clutterbuck and Sanderson 1988; Clutterbuck et al. 1989; Caldenhoven et al. 1998; Yamaguchi et al. 1999; Querfurth et al. 2000; Dyer et al. 2008; Fukushima et al. 2009; Qiu et al. 2009). However, it is possible that cytokine-induced eosinophils are crucially different from eosinophils in vivo.

GATA1 and GATA2 are in members of a family of GATA-type zinc finger transcription factors (Yamamoto et al. 1990; Ferreira et al. 2005; Shimizu et al. 2008). Targeting knockout of these genes resulted in embryonic lethality due to impaired hematopoiesis (Tsai et al. 1994; Fujiwara et al. 1996; Takahashi et al. 1997). In adult hematopoiesis, GATA2 is expressed in hematopoietic stem/progenitor cells and in immature erythroid/megakaryocyte lineage cells, while GATA1 is expressed in a later stage of erythroid/megakaryocytic cells (Weiss and Orkin 1995; Takahashi et al. 1998; Yang et al. 2000; Minegishi et al. 2003; Kobayashi-Okada et al. 2005; Suzuki et al. 2006; Muntean et al. 2007). GATA1 expression in dendritic cells has also been reported (Gutierrez et al. 2007). Both GATA1 and GATA2 are expressed in eosinophils, mast cells, and basophils (Zon et al. 1993; Harigae et al. 1998; Weiss and Orkin 1995; Yamaguchi et al. 1998; Hirasawa et al. 2002; Iwasaki et al. 2005, 2006; Takemoto et al. 2008). Maturation of mast cells and eosinophils, as well as megakaryocyte/erythroid cells, is impaired in Gata1-deicient mice (Harigae et al. 1998; Takahashi et al. 1998; Hirasawa et al. 2002; Yu et al. 2002).

Common granulocyte/monocyte progenitors produce single-lineage committed progenitors for eosinophils, mast cells and basophils (Iwasaki et al. 2005; Arinobu et al. 2009). Several transcription factors, including GATA1, GATA2, PU.1 and the C/EBP family factors regulate eosinophil development from myeloid progenitor cells (Du et al. 2002; McNagny and Graf 2002; Iwasaki et al. 2005, 2006). In the AdblGATA mouse, which lacks double GATA motifs in the Gata1 gene promoter, GATA1 expression in eosinophils is markedly decreased and eosinophils are depleted (Yu et al. 2002). However, in another report, the hematopoietic enhancer is not important while the first intron of the Gata1 gene is important for GATA1 expression in eosinophils (Guyot et al. 2004). On the other hand, the balance between GATA2 and C/EBPz expression regulates the cell-fate decision of progenitor cells (Iwasaki et al. 2006). RNA silencing and overexpression experiments demonstrate that GATA2 and C/EBPz, but not GATA1, drive eosinophil-specific gene expression (Fukushima et al. 2009; Qiu et al. 2009). These data suggest that GATA1 and GATA2 might regulate common but separate pathways of eosinophil development, and that expression of these genes might be used as a tool for isolating eosinophils.

In this study we aimed to characterize the eosinophil differentiation pathway by utilizing reporter mice that express green or red fluorescent protein (GFP and RFP, respectively) under the regulation of the Gata1 and Gata2 genes. To monitor the expression of Gata1 and Gata2 genes simultaneously, we also generated a compound reporter mouse line (G1-Red:G2-GFP mouse line) that expresses red and green fluorescent proteins under the control of the Gata1 and Gata2 regulatory domains, respectively. The G1-Red:G2-GFP mice were subjected to intranasal OVA challenge to monitor the reactivity of eosinophils during various stages of development. These results indicated that G1-Red:G2-GFP transgenic mice might be a useful tool for studies of eosinophils in allergic response and infectious diseases.

**Methods**

**Mice**

To construct the G1-Red transgene, Gata1-HRD (Onodera et al. 1997; Suzuki et al. 2003) was ligated to DsRed2 cDNA (Clontech, Mountain View, CA). We established four lines of G1-Red transgenic mice and the highest DsRed-expressing line was mainly used in this study. For screening G1-Red transgenic mice, tail DNA was extracted and the DsRed2 transgene was detected by polymerase chain reaction (PCR) using a pair of primers, Red-S (5'-ACGGCTTCAAGG TGTACGTG-3') and Red-AS (5'-CTCCACGCCATGCTTCT-3'). Both G1-GFP (Gata1-HRD-GFP) mice and G2-GFP (Gata2 EIS-KI) mice have been described previously (Suzuki et al. 2003, 2006). To generate G1-Red:G2-GFP mice, G1-Red mice and G2-GFP mice were mated. All mice were treated according to the regulations of the Standards for Human Care and Use of Laboratory Animals of the University of Tsukuba. Mice were analyzed from 9 to 16 weeks of age.

**Flow cytometry and cell sorting**

Cell sorting and marker analysis were performed using FACS Vantage SE and Cell Quest software (Becton Dickinson, San Jose, CA). Mononuclear cell suspensions from bone marrow, peripheral blood, and bronchoalveolar lavage fluid (BALF) of the transgenic mice were prepared and incubated with biotinylated monoclonal antibodies recognizing Ter119, B220, CD4, CD8 (for the lymphoid and erythroid markers, LyE), and CD71. Cells negative for both markers (LyE/CD71 cells) were enriched by magnetic negative selection using streptavidin-conjugated magnetic beads (BioMag; Polysciences, Warrington, PA), followed by staining with allophycocyanin (APC-
Eosinophils in Gata1-Reporter Transgenic Mice

conjugated anti-c-Kit antibodies, streptavidin-conjugated phycoerythrin (PE)-Texas Red and propidium iodide (PI; Sigma, St Louis, MO, USA). For G1-GFP and G2-GFP mice, enriched LyE− cells were stained with PE-conjugated anti-CD71 antibody, APC-conjugated anti-c-Kit antibody, streptavidin-conjugated PE-Texas Red, and PI. For G1-Red mice, enriched LyE− cells were stained with fluorescein isothiocyanate (FITC)-conjugated anti-CD71 antibody, APC-conjugated anti-c-Kit antibody, streptavidin-conjugated PE-Texas Red, and PI. All antibodies and streptavidin-conjugated fluorochromes were purchased from BD Pharmingen (San Diego, CA).

Cytochemistry

Flow-sorted cells were subjected to cytospin and analyzed for Wright-Giemsa (MUTO, Tokyo) and EoProbe (BioFX, Owings Mills, MD) staining. Cells positive for EoProbe were observed under the fluorescent microscope (Leica Microsystems, Wetzlar, Germany) after exposure to 561-nm wavelength excitation for 10 seconds to quenching auto fluorescence.

Colony assay

Sorted cells were cultured in 1 ml of 0.8% methylcellulose medium containing 30% fetal bovine serum (FBS). For detection of eosinophyl colony-forming units, medium was supplemented with 100 ng/ml of IL-5 (R&D Systems, Minneapolis, MN) and 100 ng/ml of stem cell factor (SCF) (PeproTech, Rocky Hill, NJ). Single-cell derived colonies were counted after 9 days of culturing, and photographs of some of growing colonies were taken everyday during the 14-day cultivation by a multi-color and fixed point observation system of a BZ-8000 fluorescent microscope (Keyence, Osaka, Japan).

Quantitative RT-PCR

Total RNA was extracted from 5,000 flow-sorted cells using an RNeasy kit (Qiagen, Basel, Switzerland) and reverse-transcribed by a Senscript RT Kit (Qiagen) with random hexamers. Quantitative PCR samples were analyzed by either SYBR Green or fluorescent probe systems (Eurogentec, Seraing, Belgium) with the gene-specific primers listed in Table 1 using an ABI PRISM 7700 Sequence Detector (Applied Biosystems, Foster City, CA). Glyceraldehyde phosphate dehydrogenase (GAPDH) mRNA levels were used as internal controls.

Allergen sensitization and challenge

Age-matched (9- to 16-week old) G1-Red;G2-GFP mice, which were back-crossed with Balb/c mice more than 6 times, were sensitized and challenged with chicken ovalbumin (OVA) as described previously (Sakai et al. 1999) with some modifications. Briefly, on days 0 and 7, mice were intraperitoneally injected with 100 μg of OVA (crude grade IV; Sigma, St. Louis, MO), which was emulsified in 1 mg of aluminum hydroxide/magnesium hydroxide (Pierce, Rockford, IL). The sensitized mice were intranasally challenged with 15 μg of OVA in 30 μl of saline on days 14, 15, and 16. On day 18, peripheral blood cells were collected through the retro-orbital plexus after anesthesia, and the BALF-derived cells were obtained from the tracheae by lavaging the lungs 3 times with 0.5 ml of ice-cold PBS containing 2% FBS.

Results

Isolation of eosinophils from bone marrow using Gata1-reporter expression

We first attempted to isolate eosinophils from the bone marrow of G1-GFP transgenic mice, which express GFP under the control of Gata1-HRD (Suzuki et al. 2003). After magnetic-bead depletion of Ter119-, B220-, CD4- or CD8-
expressing cells (LyE⁻), we isolated LyE⁻/c-Kit⁻/CD71⁻/G1-GFP⁺/c-Kit⁻/CD71⁻/G1-GFP⁺ cells (G1-R1 fraction; Fig. 1A). Morphological examination by Wright-Giemsa staining demonstrated that the cells in the G1-R1 fraction contained segmented nuclei and distinct large pink (eosinophilic) granules in the cytoplasm (Fig. 1B, upper left). Cells in each fraction were analyzed with EoProbe staining, which stains the eosinophil-specific basic cytoplasm by red fluorescence. Using this technique, red fluorescence was markedly observed in the G1-R1 fraction of isolated cells (Fig. 1B). In the G1-R1 fraction, strong red fluorescence was observed in over 80% of the cells, and modest or weak fluorescence was detected in the remaining 20% of cells (Fig. 1B). The data suggest that eosinophils are highly enriched in the G1-R1 fraction of the G1-GFP mouse bone marrow. Cells with basophil-like morphology were not readily observed in the G1-R1 fraction.

We compared mRNA expression in G1-R1 (LyE⁻/c-Kit⁻/CD71⁻/G1-GFP⁺), G1-R2 (LyE⁻/c-Kit⁻/CD71⁻), and G1-R3 (LyE⁻/c-Kit⁻/CD71⁻/G1-GFP⁻) fractions by quantitative RT-PCR (Fig. 1C). Gata1 mRNA was expressed in the G1-R1 fraction, albeit lower than in the G1-R2 fraction. High levels of Gata2, IL-5Rα, MBP and EPX mRNA expression were identified specifically in the G1-R1 fraction, while Fog1 mRNA was not readily detected in the G1-R1 fraction. In contrast, Gata1 and Fog1 mRNAs were abundantly expressed in the G1-R2 fraction, which contains immature erythroid cells (Suzuki et al. 2003). FOG-1 (Friend of GATA-1) is one of the well-studied cofactors of GATA1 (Chang et al. 2002) that are expressed in erythroid/megakaryocyte lineage cells, but not in eosinophils (Querfurth et al. 2000). These results thus demonstrate that G1-GFP is a useful marker for eosinophil isolation from the bone marrow, and that cells in the eosinophil lineage are highly enriched in the G1-R1 fraction. It is interesting to note that, in agreement with previous reports on eosinophils (Querfurth et al. 2000; McNagny and Graf 2002; Qiu et al.
2009), both Gata1 and Gata2 mRNA was expressed in the G1-R1 eosinophilic fraction.

Simultaneous expression of Gata1 and Gata2 reporters in eosinophil colonies

Because Gata2 mRNA was detected in the G1-R1 fraction, we attempted to isolate eosinophils using reporter expression under the regulatory influence of the Gata2 gene. For this purpose, we utilized G2-GFP mice in which the GFP gene is knocked into the Gata2 gene 1S exon (Suzuki et al. 2006). GFP expression in G2-GFP mice has been previously shown to recapitulate GATA2 expression in hematopoietic stem/progenitor cells (Suzuki et al. 2006). We also generated a transgenic mouse line that expresses red fluorescent protein under the regulatory influence of Gata1-HRD (G1-Red mouse line). To monitor Gata1 and Gata2 reporter expression in individual mice, we crossed G1-Red mice with G2-GFP mice to obtain G1-Red:G2-GFP mice.

In eosinophil colony forming assays, we found that LyE/c-Kit/CD71− cells from the bone marrow formed no eosinophil colonies, indicating that these cells were further differentiated from the colony-forming progenitor stage. In contrast, eosinophil colonies were formed from LyE/c-Kit+/CD71− mononuclear cells (data not shown). During growth of the eosinophil colonies from LyE/c-Kit+/CD71− cells, each single colony simultaneously began to emit both green and red fluorescence, and some of cells in the colonies co-expressed G1-Red and G2-GFP (Fig. 2A). This observation suggests that both GATA1 and GATA2 are simultaneously expressed in proliferating eosinophils.

The Gata2 reporter is expressed by a small portion of eosinophil lineage cells

We identified GFP-positive cells from the bone marrow of G2-GFP mice as a small population (G2-R1, 0.7%; Fig. 2B) in the LyE/c-Kit+/CD71− fraction. The G2-R1 fraction contained cells with pink granules in the cytoplasm (with Wright-Giemsa staining) and with EoProbe red fluorescence (Fig. 2C); however, the number of granules was less and intensity of the fluorescence was weaker in the G1G2-R1 fraction (G1-Red, G2-GFP; Fig. 3B, left panels). These cells were densely stained with EoProbe (Fig. 3B, right panels), indicating that this G1G2-R3 fraction contains eosinophils, as is the case for the G1-R1 fraction. Cells in the G1G2-R2 fraction (G1 Red/G2-GFP) also possessed pink granules by Wright-Giemsa stain and showed fluorescence with EoProbe (Fig. 3B). In contrast, cells in G1G2-R1 fraction (G1-Red/G2-GFP) contain a much lower number of eosinophilic granules, if any, and were stained only weakly with EoProbe (Fig. 3B). More than 80% of cells were positive for EoProbe in every eosinophilic fraction (G1G2-R1, -R2 and -R3), though the fluorescent intensities of the staining were different among these 3 fractions. Cells with the brightest staining were observed in the G1G2-R3 fraction, while most of cells were dully stained in the G1G2-R1 fraction (Fig. 3B). These results seem to reflect a stepwise maturation of eosinophils, which progresses from the G1G2-R1 to G1G2-R3 fractions through G1G2-R2 fraction. However, further experiments are required for solid confirmation of this observation.

Consistent with the results from RT-PCR experiments in G1-GFP mice (see Fig. 1), expression of eosinophil-specific genes were detected in G1-Red− fractions (G1G2-R2 and G1G2-R3; Fig. 3C). Expression of the C/EBPα and CD34 genes were high in G2-GFP+ fractions (G1G2-R1 and G1G2-R2; Fig. 3C), suggesting that G2-GFP expression might identify immature hematopoietic cells. Since detected expression levels of Gata1 mRNA in G1-Red−negative G1G2-R1 (G1G2-R1 fraction) was similar to the G1G2-R3 fraction positive for G1-Red expression (Fig. 3C), Gata1-HRD reporter transgene expression might not fully represent endogenous Gata1 gene expression, as we mentioned in our previous report (Suzuki et al. 2003). These results thus reinforce that there are at least three flow-sorted fractions corresponding to relatively differentiated eosinophil stages after the colony-forming stages. These three eosinophil fractions are detectable by using the expression patterns of Gata1 and Gata2 genes.
Expression of Gata1 and Gata2 reporters in peripheral blood

We next analyzed fluorescent expression of G1-Red and G2-GFP in peripheral blood eosinophils. As is the case with bone marrow cells, the LyE/CD71−/c-Kit+ cell fraction in peripheral blood from G1-Red:G2-GFP mice was divided into four subfractions by expression of G1-Red and G2-GFP (G1G2-R1 to G1G2-R4 fractions; Fig. 4A). Cells isolated from each fraction were stained by Wright-Giemsa and EoProbe (Fig. 4B) and the results demonstrated that the percentage of eosinophils in the G1G2-R3 fraction was low (20% to 40%). This is unlike the bone marrow G1G2-R3 fraction, in which more than 80% of cells belong to the eosinophil lineage. The majority of cells in any of the
Fig. 3. Isolation of eosinophils from bone marrow by combinatorial monitoring of Gata1- and Gata2- reporter expression. (A) LyE-/c-Kit+/CD71- hematopoietic mononuclear cells from the G1-Red:G2-GFP mouse bone marrow were divided into four sub-fractions with DsRed2 (G1-Red) and GFP (G2-GFP) expression. The percentage of cells in each quadrant of the data from flow cytometry (left) is represented in the right boxes with the name and position of each region. (B) Wright-Giemsa (left panels) and EoProbe (right panels) staining of cells in each region. Cells in G1G2-R1 (lower right), -R2 (upper right), -R3 (upper left) and -R4 (lower left) are shown. The position of each panel is represented in A. Scale bars are 10 µm. (C) Relative mRNA expression levels of indicated genes in cells from each region were measured by quantitative RT-PCR. The results were normalized to the level of GAPDH mRNA and are shown with the standard deviation from 3 or more independent experiments.
K. Kim et al.

G1G2-R1, G1G2-R2 and G1G2-R3 fractions of peripheral blood were lymphocytes or neutrophils (Fig. 4B), which might be contamination during flow-cytometry sorting due to the low number of cells in these fractions. These results indicate that fully differentiated eosinophils (G1G2-R3 fraction) tend to migrate from the bone marrow to peripheral blood.

**Eosinophils increased in number in response to allergen challenge**

Eosinophils in G1-Red:G2-GFP mice were analyzed using an experimental model of acute asthma (Sakai et al. 1999) to study how eosinophils react to allergen challenge. In the bone marrow, the populations of the G1G2-R2 and G1G2-R3 eosinophils significantly increased as a result of OVA challenge (Fig. 5A and B). Morphological analyses showed that the percentages of eosinophils in these two fractions were not altered by OVA challenge (more than 80%). Additionally, the G1G2-R3 fraction in peripheral blood was increased under the acute asthma condition (Fig. 5A and B). Although we could not efficiently enrich eosinophils from peripheral blood, the increase in cell population in the peripheral blood G1G2-R3 fraction most likely reflects an increase in the number of eosinophils, because the rate of eosinophil concentration in the G1G2-R3 fraction was elevated 2 to 3 fold (approximately 60%) after OVA challenge (data not shown). While there were few cells in the G1G2-R3 (G1-Red+/G2-GFP−) fraction of BALF under normal conditions (Fig. 5A and B) (Stevens et al. 2007), the apparent cell population was increased in the G1G2-R3 fraction by induction of asthma (Fig. 5A and B). Wright-Giemsa staining confirmed that the cells in the G1G2-R3 fraction of BALF, both before and after OVA challenge, were mostly (more than 80%) eosinophils (data not shown). Taken together, these results show that fully differentiated eosinophils (G1G2-R3 fraction) markedly increase in number and migrate into the lungs in response to allergen challenge. Furthermore, the data suggest that G1-Red:G2-GFP mice will be a useful tool in investigating the pathophysiology of allergic disease.
Discussion

In this study, we established a flow cytometry-based system for eosinophil isolation using *Gata1-HRD* reporter transgenic mouse lines. Both G1-GFP and G1-Red fluorescence in the LyE⁻/c-Kit⁻/CD71⁻ fraction efficiently enriched eosinophils in the bone marrow and BALF.

GATA1 expression is restricted to hematopoietic cells and Sertoli cells in the testis (Yamamoto et al. 1990; Ito et al. 1993; Yomogida et al. 1994; Ferreira et al. 2005; Shimizu...
et al. 2008). *Gata1-HRD* drives expression of GATA1 in erythrocytes/megakaryocyte, basophil, mast cell, and eosinophil cell lineages (Onodera et al. 1997; Suzuki et al. 2003). To achieve efficient fractionation of eosinophils in the bone marrow cell fraction expressing the *Gata1-HRD* transgene, lymphoid cells (positive for CD4, CD8 or B220), erythroid cells (positive for Ter119 and/or CD71) and c-Kit+ cells (including hematopoietic progenitors, mast cells and basophils) were eliminated by negative selection with the appropriate antibodies. Megakaryocytes were scarcely detected in the flow cytometry of bone marrow preparations in this study, probably due to their bulky and adhesive cytoplasm. Thus, *in vivo* eosinophils were effectively collected as G1-GFP+ or G1-Red+ cells in the LyE/c-Kit+/CD71- fraction from hematopoietic cells in the bone marrow of mice under normal physiological conditions.

We propose that our method of using *Gata1-HRD* derived fluorescence will be useful in detection and isolation of tissue-infiltrating eosinophils. Eosinophils are easily detected by morphological examination of smear samples from bone marrow and peripheral blood; nevertheless it is not easy to estimate the extent of eosinophil infiltration in inflamed lungs (Foster et al. 1996; Kopf et al. 1996; Shen et al. 2003; Ishizaki et al. 2006). Preparation of mononuclear cell suspensions of the lung is an established technique (Stevens et al. 2007) and several methods to analyze eosinophils in these parenchymal cell suspensions have been reported (Hansel et al. 1991; Du et al. 2002; Iwasaki et al. 2005; Ishizaki et al. 2006; Stevens et al. 2007; Fukushima et al. 2009; Mori et al. 2009; Shen et al. 2009). In previous approaches, eosinophils were fractionated according to specific gravity (Gärtner 1980) or their reactivity to specific antibodies against surface marker antigens with/without forward/side scatter gating (Hansel et al. 1991; Du et al. 2002; Ishizaki et al. 2006; Rothenberg and Hogan 2006). In contrast, we used monoclonal antibodies only for negative selection. Thus, our system minimizes the possibility of cross-reaction of adopted antibodies with hematopoietic or non-hematopoietic cells and of aberrant signal-transductions from antigen-antibody reactions.

As mentioned above, fluorescent proteins expressed by the *Gata1-HRD* transgenes efficiently labeled mature eosinophils in the LyE/c-Kit+/CD71- fraction, while eosinophil progenitors (EoPs) harboring a colony-forming potential were *Gata1-HRD* reporter–negative in the LyE/c-Kit+/CD71- fraction of bone marrow hematopoietic cells. Consistent with this finding, it has been reported that EoPs are included in c-Kit+ fraction (Iwasaki et al. 2005; Arinobu et al. 2009; Mori et al. 2009), and that Gata1 gene expression in EoP is low compared with other Gata1-expressing cells, including progenitors for basophils, mast cells, megakaryocytes or erythroid cells (Iwasaki et al. 2006). Since *Gata1-HRD* is not active in the early progenitor stage of erythroid lineage cells (Suzuki et al. 2003), this 8 kb of the gene regulatory domain may also not be sufficient for regulation of the Gata1 gene expression in EoP.

Time-lapse observation of eosinophils during colony formation showed simultaneous fluorescent emission of G1-Red and G2-GFP, implying simultaneous expression of the Gata1 and Gata2 genes in growing eosinophils. These data were supported by data from flow cytometry analysis of G1-Red:G2-GFP mice, which distinguished G1-Red+/G2-GFP+ cells (G1G2-R2 fraction in Fig. 3A) in LyE/c-Kit+/CD71- bone marrow cells. In addition, several reports have demonstrated simultaneous expression of the Gata1 and Gata2 genes in EoP fractionated with an anti-IL-5Rα antibody from mouse bone marrow (Iwasaki et al. 2005, 2006; Mori et al. 2009) or in eosinophils obtained by culturing progenitor cells (Qu et al. 2009). However, the major eosinophilic fraction in G1-Red:G2-GFP mouse bone marrow is the G1-Red+/G2-GFP- (G1G2-R3) fraction, in which the Gata2 mRNA expression level is very low or undetectable by quantitative RT-PCR analysis. We thus suggest that the Gata2 gene is transiently expressed during growth of eosinophils, and that expression is diminished in cells in the G1G2-R3 fraction, which are morphologically characteristic of mature eosinophils.

During hematopoietic development, GATA2 expression is first identified in hematopoietic stem cells and persists in multi-potential progenitors (Minegishi et al. 1998; Iwasaki et al. 2005; Suzuki et al. 2006). GATA2 up-regulates transcription of the Gata1 gene in an early stage of erythroid differentiation (Kobayashi-Osaki et al. 2005) and increased GATA1 expression finally represses Gata2 gene transcription in a later stage of erythroid cells (Grass et al. 2003; Johnson et al. 2007). In eosinophil differentiation, it is plausible to speculate that Gata2 gene expression is diminished by GATA1 in a similar way with erythroid cells. Although FOG-1 is essential for repression of the Gata2 gene expression by GATA1 in erythroid lineages (Querfurth et al. 2000; Johnson et al. 2007), *Fog1* mRNA is not expressed in eosinophils. Therefore, we expect that GATA1 might repress the Gata2 gene expression during maturation of eosinophils in a FOG-1-independent fashion.

In this study, we have developed a new method to efficiently fractionate mature eosinophils from bone marrow and BALF by exploiting *Gata1-HRD*-reporter expression as a useful marker of mature eosinophils. We propose that this method may be useful in pathophysiological studies of eosinophils in hematopoietic and parenchymal tissues.
