Hypertension and osteoporosis are two common diseases in the elderly population. Recently, reduced bone mineral density has been found in hypertensive patients compared with healthy controls. Reduced bone mineral density is associated with increased arterial stiffness in chronic dialysis patients and healthy postmenopausal women. However, relationships between bone mineral density and arterial stiffness in hypertensive patients have not been fully assessed. We examined the relationships between bone mineral density and both arterial stiffness and nutritional status in 52 hypertensive patients (27 male and 25 female subjects; mean age 71 ± 8 years) who had been treated with antihypertensive drugs for at least one year. The bone mineral density of the calcaneus was measured with a quantitative ultrasound measurement device, and the stiffness index was determined as a parameter of the bone mineral density. We measured the cardio-ankle vascular index (CAVI) to assess arterial stiffness and used the serum albumin to assess nutritional status. Increased arterial stiffness as assessed with CAVI is associated with reduced bone mineral density \( r = -0.289, p = 0.038 \). However, the correlation between CAVI and bone mineral density is not as strong as the correlation between serum albumin and bone mineral density \( r = 0.501, p < 0.001 \).

In conclusion, nutritional status is an important indicator of bone mineral density in hypertensive patients. Moreover, increased arterial stiffness is associated with reduced bone mineral density in hypertensive patients. Therefore, hypertensive patients with increased arterial stiffness may have a high risk of bone fracture due to osteoporosis.

Keywords: hypertension; bone mineral density; arterial stiffness; cardio-ankle vascular index

Recently, the cardio-ankle vascular index (CAVI), which is a parameter derived from pulse wave velocity, has been used to assess arterial stiffness (Shirai et al. 2006; Miyashita et al. 2010). In the present study, we examined the association between arterial stiffness as assessed by CAVI and bone mineral density by comparing it with the association between nutritional status and bone mineral density in treated hypertensive patients.

Methods

Subjects

The study subjects were 52 patients (27 male, 25 female; mean age 71 ± 8 years, range 50-83 years) who had been diagnosed with hypertension at Kagawa University Hospital and who had regularly visited the outpatient clinic from April, 2009 through August, 2010. Hypertension was defined as systolic blood pressure ≥ 140 mmHg and/or diastolic blood pressure ≥ 90 mmHg. Blood pressure was determined using the conventional cuff method. All patients were treated with at least one antihypertensive drug. For at least one year during their enrollment in this study, the antihypertensive drugs did not change for any patients. Patients with a history of heart failure or obvious heart disease were excluded. None of the patients had a history of atherosclerotic cardiovascular disease or stroke. Osteoporosis was assessed by measuring bone mineral density just after measurement of CAVI. Blood samples were taken in the morning after a 12-hour overnight fast. Plasma total cholesterol, triglyceride, and high-density lipoprotein cholesterol (HDL-C), and serum uric acid, creatinine, albumin, and hemoglobin were measured by standard laboratory techniques. The glomerular filtration rate was estimated from the equation for Japanese patients, recently proposed by a working group of the Japanese Chronic Kidney Disease Initiative (Imai et al. 2008) as follows:

\[ eGFR = 194 \times \text{age}^{0.267} \times (\text{serum creatinine})^{1.094} (\times 0.739 \text{ if female}). \]

Patients with renal dysfunction whose serum creatinine levels were ≥ 1.2 mg/dL were excluded from the present study. Relationships between bone mineral density and various clinical characteristics, including blood pressure, CAVI, and laboratory data, were analyzed. This protocol was approved by the Ethics Committee of Kagawa University. Informed consent was obtained from all participants.

Assessment of arterial stiffness by measuring CAVI

CAVI was measured using an automatic vascular screening system (VaSera VS-1000; Fukuda Densi, Tokyo, Japan) with the patient resting in a supine position. Pulse wave velocity (PWV) was obtained by dividing the vascular length by the time it took for the pulse wave to propagate from the aortic valve to the ankle. Systolic blood pressure (SBP) and diastolic blood pressure (DBP) were measured at the brachial artery. The formula used to calculate CAVI was as follows: CAVI = \[a \times (\frac{\Delta P}{\Delta P}) \times \ln \left(\frac{\text{SBP}}{\text{DBP}}\right) \times \text{PWV}^2\] + \[b\), where \[\Delta P\] is SBP-DBP, \(\rho\) is blood density, and \(a\) and \(b\) are scale conversion constants to match aortic PWV. The principle underlying CAVI has been described previously (Shirai et al. 2006). The equation is derived from Bramwell-Hill’s equation and the stiffness parameter \(B\), and CAVI was adjusted for blood pressure based on the stiffness parameter \(B\). Therefore, CAVI reflects the stiffness of the aorta, femoral artery and tibial artery as a whole, and theoretically, it is not affected by blood pressure. All these measurements and calculations were performed in VaSera VS-1000. Electrocardiogram (ECG) electrodes were placed on both wrists, a microphone for detecting heart sounds was placed on the sternum, and cuffs were wrapped around both arms and both ankles. After automatic measurements, the values of right and left CAVI were calculated. The averages of the right and left CAVIs were used for analysis.

Measurement of bone mineral density

The bone mineral density of the right calcaneus (Guglielmi and de Terlizzi 2009; Iida et al. 2010; Mergler et al. 2010) was measured using a quantitative ultrasound measurement device (A-1000 EXPRESS/InSight, GE Healthcare) with the patient resting in a sitting position just after the measurement of CAVI. The stiffness index, which is a parameter of bone mineral density, was determined by the following equation (Yoshimi et al. 2001; Yahata et al. 2002; Zhang et al. 2003; Iida et al. 2010):

\[ \text{The stiffness index} = 0.67 \times (\text{broadband ultrasound attenuation}) + 0.28 \times (\text{speed of sound}) - 420. \]

In addition, in order to assess the degree of reduction of bone mineral density, this machine was able to calculate values compared with average values for young people in their 20’s. Furthermore, this machine was able to provide values compared with average values for people of the same age, in order to avoid the influences of aging.

Statistical analysis

Data are expressed as means ± s.d. Statistical analysis was performed using the SPSS software package (SPSS, Chicago, IL, USA). Linear regression analysis was performed to evaluate the associations between bone mineral density and other variables. Step-wise multiple regression analysis was performed to determine the correlation between bone mineral density and each independent variable. Values of \(p < 0.05\) were considered to indicate statistical significance.

Results

Clinical characteristics of subjects

The clinical parameters of the study subjects are summarized in Table 1. The mean systolic brachial blood pressure of all subjects was not particularly high (133 ± 19 mmHg) because all patients’ blood pressure was appropriately controlled by medication. The subjects were considerably old (71 ± 8 years). Their mean value of CAVI (9.2 ± 1.4) was high, indicating arterial stiffening. The subjects’ mean stiffness index for bone mineral density was 71 ± 18. This mean index value was 72 ± 18% of the mean values for young people in their 20’s, reflecting the effect of aging on the subjects’ bone mineral density. However, the mean index value was 96 ± 23% of the mean value for the same-age population, indicating that the reduced bone mineral bone density was due to other causes in addition to aging.

Correlation between bone mineral density and clinical variables

Linear regression analysis was performed to examine the relationships between bone mineral density (the stiff-
Bone Mineral Density and Arterial Stiffness

Among the clinical variables, age ($r = -0.446$, $p = 0.001$), body height ($r = 0.307$, $p = 0.027$), body weight ($r = 0.276$, $p = 0.048$), serum albumin ($r = 0.501$, $p < 0.001$), hemoglobin ($r = 0.476$, $p < 0.001$), and CAVI ($r = -0.289$, $p = 0.038$) showed significant correlations with the stiffness index of bone mineral density. Among the clinical parameters, serum albumin demonstrated the highest correlation with the stiffness index of bone mineral density. Although the correlation between CAVI and bone mineral density was statistically significant, the correlation was not as strong as that between serum albumin and bone mineral density (Fig. 1).

Assessment of the factors related to bone mineral density

Stepwise multiple regression analysis was performed to identify which clinical parameters were independently associated with the stiffness index of bone mineral density. Stepwise multiple regression analysis was performed for variables showing significant correlations with the stiffness index of bone mineral density in the linear regression analysis in Table 2. This analysis indicated that serum albumin ($\beta$ coefficient $= 0.361$, $p = 0.009$) and hemoglobin ($\beta$ coefficient $= 0.321$, $p = 0.019$) were independently associated with the stiffness index of bone mineral density (Table 3).

Discussion

The present study compares CAVI and nutritional status data to identify the association between arterial stiffness and bone mineral density in treated hypertensive patients. The data indicate that increased arterial stiffness as assessed by CAVI is associated with reduced bone mineral density. However, the correlation between CAVI and bone mineral density was not as strong as that between serum albumin and bone mineral density.

Although previous studies (Aoki et al. 2009; Benetos et al. 2009; Mikumo et al. 2009; Seo et al. 2009) have shown that reduced bone mineral density is associated with arterial stiffening in chronic dialysis patients and healthy postmenopausal women, there are no data regarding the association between bone mineral density and arterial stiffness in hypertensive patients without overt cardiovascular diseases. Our results indicate an association between bone mineral density and arterial stiffness in hypertensive...
patients. Our results provide the new finding that nutritional status, including serum albumin and hemoglobin, is a more important determinant of bone mineral density than arterial stiffness in hypertensive patients. Therefore, improvement of nutritional status may be important to prevent bone fractures due to osteoporosis in hypertensive patients. However, our results suggest that increased arterial stiffness is associated with reduced bone mineral density to some degree. Therefore, hypertensive patients with increased arterial stiffness may have a high risk of bone fractures due to osteoporosis. In the present study, arterial stiffness was assessed by CA VI, which is less influenced by blood pressure (Shirai et al. 2006). In addition, the blood pressure of participants was well controlled by medications. Therefore, the blood pressure was not correlated with bone mineral density, whereas CA VI was (Table 2).

It is well known that nutrition status, including serum albumin, dietary protein, and Vitamin D, is a predictor of bone mineral density (Bawa 2010; Gutiérrez et al. 2010; Jeong et al. 2010; Jesudason and Clifton 2010). Our data are in agreement with these previous reports (Jeong et al. 2010; Jesudason and Clifton 2010). Our results suggest that the role of nutrition in bone health is important in treated hypertensive patients as well as chronic dialysis patients or healthy postmenopausal women. However, angiotensin-converting enzyme (ACE) inhibitors have been recently reported to reduce the risk of bone fractures (Lynn et al. 2006; Rejnmark et al. 2006). In addition, a recent experimental study has demonstrated that angiotensin II activates osteoclasts, leading to osteoporosis (Shimizu et al. 2008) and that ACE inhibitors attenuate osteoporosis in spontaneously hypertensive rats (Shimizu et al. 2009). An activated renin-angiotensin system is well known to be a promoting factor of atherosclerosis including arterial stiffening (Shapiro et al. 2008; Sie et al. 2009). The activated renin-angiotensin system in hypertensive patients may have played an important role in the association between reduced bone mineral density and increased arterial stiffness in the subjects of the present study. The participants of the present study included 33 patients with renin-angiotensin system (RAS) inhibitors and 19 patients without RAS inhibitors. The bone mineral density did not differ between patients with RAS inhibitors (72 ± 19) and patients without RAS inhibitors (70 ± 18). However, the present study was a cross-sectional study. A follow-up study during antihypertensive treatment may be needed to assess the influence of RAS inhibitors on bone mineral density.

The present study has several limitations. First, we did not measure serum levels of ionized calcium and parathyroid hormone, which might suggest that hypertension is associated with not only increased arterial stiffness but also osteoporosis. Second, we did not assess nutrition habits, including dietary protein and Vitamin D, which may influence bone mineral density. In addition, we did not assess the effects of lifestyle modification such as sodium reduction, which may reduce arterial stiffness, because the present study was a cross-sectional study. Third, we used an ultrasound device to measures bone mineral density in the present study. Although ultrasound measurement is a quick and non-stressful method, bone mineral density is usually measured by dual-energy X-ray absorptiometry in the clinical settings. However a previous study (Iida et al. 2010) demonstrated that bone mineral density by ultrasound measurement was significantly correlated with bone mineral density on dual-energy X-ray absorptiometry. Finally, it was difficult to determine the difference between genders because the study population of the present study was small. However, the correlation between bone mineral density and CAVI was statistically significant in 27 male patients ($r = -0.542, p = 0.004$), but was insignificant in 25 female patients ($r = -0.131, p = 0.531$) in the present study. A further study containing a large number of male and female

patients may be needed to elucidate the differences between genders.

In conclusion, nutritional status may be a more important indicator of bone mineral density in hypertensive patients than arterial stiffness. However, increased arterial stiffness is associated with reduced bone mineral density to some degree in hypertensive patients. Therefore, hypertensive patients with increased arterial stiffness may have a high risk of bone fractures due to osteoporosis.
