because the patients of this group have normal or low aldosterone secretion rates (Ledingham et al. 1967). However, the fact that a mineralocorticoid inhibitor spironolactone or an inhibitor of adrenal steroidogenesis aminoglutethimide lowers blood pressure in patients with suppressed PRA suggests that mineralocorticoid excess may somehow be involved in the mechanism of suppressed renin secretion (Woods et al. 1969). Several hormones with mineralocorticoid activity have been incriminated in the pathogenesis of low PRA essential hypertension by many researchers (Melby et al. 1971; Sennett et al. 1975). But there is little evidence of the involvement of these substances.

Recently, Padfield et al. (1975) reported that low PRA hypertension is a stage in the course of essential hypertension, because PRA falls with the duration of this disease. To elucidate the problem whether low PRA essential hypertension is a result of the long-term effects of high blood pressure on the kidney or not, the relationship between renin, hypertension, and its duration was studied. Padfield’s hypothesis was not supported. We report our results below.

**Patients and Methods**

One hundred thirty-nine healthy normotensive subjects and 200 patients with essential hypertension were studied. The normotensive individuals ranged in age from 11 to 81 years. Fifty-seven were men and 82 were women. Hypertensive patients ranged in age from 11 to 71 years. One hundred thirty-eight were men and 62 were women. The diagnosis of essential hypertension was established by history, physical examination, routine laboratory tests, intravenous pyelography, renal arteriography and determinations of plasma 11-OHCS, aldosterone, and urinary catecholamines or vanillyl mandelic acid. Renal arteriography was done whenever the patients had abnormal findings in intravenous pyelography and PRA values.

Antihypertensive drugs were discontinued at least two weeks before the study, and sodium intake (approximately 250 mmoles per day) was allowed for at least one week before PRA determination. Sampling of blood was done with fasting patients kept in recumbent position for one hr in the morning. To evaluate the reaction of renin secretion to the load, sampling of blood was done after intravenous injection of furosemide (1 mg/kg) and taking two-hour’s upright posture. PRA in peripheral blood was determined by a sensitive method of angiotensin I radioimmunoassay (Abe et al. 1972).

One milliliter of plasma was incubated at 37°C at pH 5.5 for 6 hr with disodium ethylene diamine tetraacetic acid (EDTA) and diisopropyl fluorophosphoate (DFP). The sample was then diluted tenfold with physiologic saline, and heated in boiling water bath for 5 min. After centrifugation, angiotensin I in the supernatant was assayed radioimmunologically. This method was approximately 4 times more sensitive than Haber’s method. The PRA values determined by the present method showed a good correlation with those of bioassay.

**Results**

*Renin and age*

The estimated values of resting peripheral vein PRA ranged from 2 to 36 ng/ml with a mean of 12.4 ng/ml (S.E. 0.62) in 139 control subjects and from less than 2 to 100 ng/ml with a mean of 15.6 ng/ml (S.E. 1.3) in 200 patients with essential hypertension. Fig. 1 shows the PRA levels at different ages in healthy
Low Renin Hypertension

Fig. 1. The resting PRA levels at different ages in 139 healthy persons and 200 hypertensive patients.

In healthy subjects, the mean PRA value of 42 persons aged under 19 years was 15.4 ng/ml (s.e. 1.1), 48 persons aged 20 to 29 years 12.2 ng/ml (s.e. 0.9), 20 persons aged 30 to 39 years 9.7 ng/ml (s.e. 1.1), 13 persons aged 40 to 59 years 11.0 ng/ml (s.e. 2.6), and 16 persons aged over 60 years 4.1 ng/ml (s.e. 0.6), respectively. The PRA level in younger subjects aged under 19 years was slightly higher than those in other age groups. On the contrary, the estimated values were very low in the advanced ages over 60 years. In the subjects aged from 20 to 59 years, however, no significant differences in the PRA levels were found (p>0.05).

In essential hypertension, similar relationship between renin and aging was observed. The mean PRA value of 20 cases aged under 19 years was 16.1 ng/ml (s.e. 3.3), 40 cases aged 20 to 29 years 12.9 ng/ml (s.e. 2.0), 56 cases aged 30 to 39 years 15.9 ng/ml (s.e. 2.7), 51 cases aged 40 to 49 years 18.6 ng/ml (s.e. 3.1), 24 cases aged 50 to 59 years 12.5 ng/ml (s.e. 2.2), and 5 cases aged over 60 years 4.9 ng/ml (s.e. 1.8), respectively.

As revealed in control subjects, the PRA level in older patients aged over 60 years was prominently low. In the patients aged under 59 years, however, no significant differences between renin and aging were found (p>0.05).

**Frequency distribution**

The frequency distribution of PRA for 123 normal subjects and 195 cases of essential hypertension aged under 59 years are demonstrated in Fig. 2. In normal subjects, 116 persons out of 123 (94%) had the values between 5 and 30 ng/ml. Therefore, the normal range of resting levels of PRA was defined from 5 to 30 ng/ml. In essential hypertension, an obvious deviation from the distribution curve of the control subjects was observed. The peak of the distribution curve in
control subjects was 12.5 ng/ml, while it was 7.5 ng/ml in the hypertensive group. From these results, it may be said that the resting PRA level in essential hypertension tends to be lower than that in healthy person.

Renin subgroup

One-hundred ninety-five patients with essential hypertension aged under 59 years were classified into 3 groups according to their resting PRA values. Subnormal resting PRA level was found in 44 cases (23%). The mean value was 2.5 ng/ml (s.e. 0.1) with a range of less than 2 to 4.9 ng/ml. Normal PRA level was obtained in 127 cases (65%). The mean PRA value was 12.6 ng/ml (s.e. 0.59) with a range of 5 to 30 ng/ml. The remaining 24 patients (12%) had high resting PRA values in whom the mean PRA value was 57.7 ng/ml (s.e. 4.8) with a range of 31 to 100 ng/ml.

Mean ages of renin subgroup were 38±13.2 years in low, 36±12.0 years in normal, and 34±12.7 years in high resting PRA groups. There were no significant differences among the mean ages of three groups (p>0.05). Mean values of systemic arterial pressure were 174±36.2/106.1±16.4 mmHg in the low PRA group, 183.2±29.8/108.3±16.9 mmHg in the normal PRA group and 178.3± 16.9/110.4±22.8 mmHg in the high PRA group. Among the blood pressures of three groups, significant differences were not found either (p>0.05).

Incidence of low renin at different ages

The incidences of low PRA, normal PRA, and high PRA hypertension of different ages are illustrated in Fig. 3. Twenty percent of younger patients aged under 19 years were with low PRA values. 20 to 25% of patients aged 20 to 59 years had low PRA levels. Regarding the incidence of low renin hypertension, there were no significant differences among the decades under 60 years of age (p>0.05). In this age range, 60 to 70% of patients had normal PRA levels and the incidences

- normal PRA;  
- high PRA.

Fig. 4. Reaction of PRA to the stimulation by intravenous furosemide injection followed by upright posture in 138 hypertensive patients aged 20 to 59 years. R, Resting PRA; U, PRA after the stimulation.

were not related to the age. High PRA hypertension was found in 10 to 20% of patients aged 10 to 60 years.
Renin secretion and aging

Provocation of renin secretion was studied in 38 healthy subjects aged from 20 to 58 years as controls. After the load of furosemide and upright posture, the peripheral vein blood PRA values were 47.9 ng/ml (s.e. 3.6) and 85% of cases had the PRA values within the range of 15 to 60 ng/ml. Therefore, this range of PRA was defined normal in the ages of 20 to 59 years. The provocation test of renin secretion was done in 138 cases of essential hypertension aged from 20 to 59 years. Fig. 4 shows the response of renin secretion in hypertensive patients at different ages. After the stimulation, the mean PRA value of 39 cases aged 20 to 29 years increased from 15.1 ng/ml (s.e. 3.0) to 40.0 ng/ml (s.e. 5.1), 44 cases aged 30 to 39 years increased from 10.3 ng/ml (s.e. 1.4) to 27.1 ng/ml (s.e. 3.9), 39 cases aged 40 to 49 years increased from 12.9 ng/ml (s.e. 3.4) to 30.1 ng/ml (s.e. 4.5), and 16 cases aged 50 to 59 years increased from 11.4 ng/ml (s.e. 2.4) to 19.6 ng/ml (s.e. 3.3), respectively. Contrary to the results in the resting peripheral vein PRA levels, an apparent decrease in the renin secretion with the age was found. There was a significant difference in the response of renin secretion between the patients aged 20 to 29 years and those aged 30 to 59 years (0.05 > p > 0.01). All hypertensive patients were classified into 3 groups according to their responses in renin secretion. Fifty-nine patients (42.8%) out of 138 did not respond to the stimulus, in whom the mean PRA were 4.8 ng/ml (s.e. 0.24) at rest and 8.6 ng/ml (s.e. 0.34) after the load. Normal response of renin secretion was found in 58 patients (42.0%), in whom PRA values increased from 14.1 ng/ml (s.e. 1.3) to 33.8 ng/ml (s.e. 1.8). The remaining 21 patients (15.2%) showed a hyperresponse; PRA increased from 33.0 ng/ml (s.e. 5.6) to 84.2 ng/ml (s.e. 3.3). Mean ages were 38.2±10.7 years in hyporesponders, 36.8±10.1 years in normal responders and 31.1±8.1 years in the hyperresponders. There was no significant difference in mean ages between the hyporesponders and the normal responders (p > 0.05), while it was lower in the hyperresponder than the other two groups (p < 0.01).

Incidences of hyporesponder at different ages

The incidences of the hyporesponders, the normal responders and the hyperresponders of renin secretion at different ages are demonstrated in Fig. 5. The hyporesponders were found in 22% of cases aged under 19 years, 33% of cases aged 20 to 29 years, 47% of cases aged 30 to 39 years, 38% of cases aged 40 to 49 years and 56% cases aged 50 to 59 years. There was positive correlation between the incidences of hyporesponder of renin secretion and the age (r=0.886, 0.01 < p < 0.05). Higher incidences of hyporesponders was obtained in older patients, and lower incidences in younger patients. In regard to the hyperresponders, the incidence was higher in younger patients than in older patients. In the patients aged 50 to 59 years, no one showed a great response to the stimulus. The normal responders were found in 40 to 50% of patients in every decade except in the advanced ages over 60 years. There was no significant difference regarding
In the present study of hypertensive patients and the age matched control subjects, it was revealed that the incidences of low resting PRA were similar in each decade under 60 years. From this result, it seems unlikely that low renin hypertension is a stage in a long-term course of essential hypertension.

The term, low PRA hypertension, is variously used for patients with essential hypertension whose PRA is low, or renin secretion in response to the stimulus is suppressed. However, there were obvious differences between these two types of PRA patterns, because, as shown in the present study, low resting PRA hypertension was not related to the age, while the hyporesponder was apparently related to the age. There were also significant differences between the incidences of these two types of renin secretion, namely, the low PRA hypertension was found in 23% and the hyporesponder in 40% of essential hypertension.

Previously, we described that greatly increased urinary excretion of sodium by furosemide was observed in healthy persons as compared with those in essential hypertension (Memezawa et al. 1975). This result suggests that the stimulus for renin secretion through sodium and water depletion following the furosemide administration is less in essential hypertension especially in aged persons than in healthy persons, and this difference may contribute to the different incidences of hyporesponder in each decade of essential hypertension. From these reasons, it may safely be said that low PRA essential hypertension has no relation to responsiveness of renin secretion to usual stimulant of the secretion.

In addition, in our previous study (Abe et al. 1975) there was no relationship between the responsiveness of the renin secretion to furosemide injection followed by the upright posture and the hypertensive complication in the kidney and the ocular fundi, which related to only the resting PRA levels measured after overnight fasting. From these studies, it seems likely that low PRA hypertension is a
definite subgroup from the other groups of essential hypertension.
