The electronic structure of La$_{0.6}$Sr$_{0.4}$FeO$_3$ thin film on MgO substrate has been studied using resonant soft-X-ray emission spectroscopy (SXES) and X-ray absorption spectroscopy (XAS). The thin film has the mixed valence states of Fe$^{3+}$ and Fe$^{4+}$ in the ground state. The valence band is mainly composed of O 2p state hybridized with t$_{2g}$ and e$_g$ states of Fe 3d. The conduction band is composed of t$_{2g}$ and e$_g$ states of Fe 3d and hole-induced state created by Sr doping. These findings accord with the result of electronic structure expected by tight-binding calculation that included the effect of electron-electron interaction.

1. INTRODUCTION

The perovskite-oxide La$_{1-x}$Sr$_x$FeO$_3$ shows interesting physical properties as a function of composition [1-5]. LaFeO$_3$ ($x=0$) with distorted orthorhombic structure is an antiferromagnetic insulator with a high Neel temperature ($T_N=738$ K). The character of the band gap is of the charge-transfer (CT) type, and optical gap is 2.1 eV [2]. SrFeO$_3$ ($x=1$) with cubic structure is a helical antiferromagnetic metal with $T_N=134$ K. The most striking behavior is observed in the intermediate composition region with rhombohedral structure. In particular, the La$_{0.5}$Sr$_{0.5}$FeO$_3$ undergoes a metal-insulator (MI) transition at $\sim 200$ K, evidenced by a jump in the resistivity of more than 1 order of magnitude with decreasing temperature. The MI transition has been classified as charge ordering, and it shows up accompanied by antiferromagnetic spin ordering below $\sim 200$ K. The charge disproportionation, which occurs from the paramagnetic average valence state (Fe$^{3.5+}$) above $\sim 200$ K to the antiferromagnetic charge ordering state (Fe$^{3+}$:Fe$^{4+}=2:1$) below $\sim 200$ K, is closely related with the MI transition. This fact has been clarified by Mössbauer spectroscopy [1,6]. X-ray scattering, and neutron diffraction.[8]

In recent years, the electronic structures of La$_{1-x}$Sr$_x$FeO$_3$ and the related Fe compounds have refocused in research area of solid state physics [7-11]. Waday et al. has prepared the La$_{1-x}$Sr$_x$FeO$_3$ thin film by pulsed laser deposition (PLD) and studied its electronic structure by theoretical calculation and photoemission spectroscopy (PES) [10,11]. The valence band consists of the t$_{2g}$ and e$_g$ subbands of Fe 3d state hybridized with O 2p state. The valence band and core level shift to lower binding energy side with increasing x. In x $\leq$ 0.4, the Fe 3d band shifts downward relative to the Fermi level ($E_F$) by $\sim$ 1.0 eV compared with the band calculation assuming the G-type antiferromagnetic state and to form a gap of $\sim$ 1.0 eV at $E_F$. These findings indicate the existence of spectral weight transfer from below to above $E_F$ across the gap. This may attribute to a strong localization effect of doped holes due to polaron formation. Therefore, the authors believe that understanding electron correlation is also one of the most important subjects for the MI transition. However, the contribution of electron correlation energy has not been directly clarified by experimental method thus far.

In this paper, we present the soft-X-ray emission spectroscopy (SXES) and X-ray absorption spectroscopy (XAS) spectra of La$_{0.6}$Sr$_{0.4}$FeO$_3$ (LSFO) thin film. SXES is related directly to the occupied density-of-state (DOS) [12-16]. SXES detects the electronic structure of the bulk state owing to the long mean free path of the soft-X-rays. The partial-DOS (PDOS) localized at an atom can be also obtained from SXES spectra, because SXES has a clear selection rule regarding the angular momentum due to dipole selection. XAS is related directly to the unoccupied DOS. This optical process is a local process because of the localized core state. It is governed by the dipole selection rules so that XAS provides spectra related to the site- and symmetry-selected DOS.

2. EXPERIMENTAL

LSFO thin film was deposited on an MgO (100) substrate by PLD using a ceramic target. The LSFO ceramics target were synthesized by a solid state reaction method and pressed into cylinders, then sintered in air at 1200°C for 6 h. The target density was approximately 98%.

The PLD system was arranged in a symmetric configuration with a rotating substrate holder for compositional uniformed. The base pressure was ordinary $\sim 3 \times 10^{-4}$ Torr, and the substrate was inserted from a load lock chamber to main chamber a low base pressure. A KrF excimer laser ($\lambda=248$ nm) was used as the ablation beam. The repetition frequency and laser power were 5 Hz and 220 mJ, respectively [17]. The oxygen gas pressure and substrate temperature were
fixed at 10 mTorr and 700°C, respectively. The film thickness was approximately 20 nm. The prepared LSFO thin film on MgO (100) substrate exhibited the c-axis orientation.

The XAS and SXES spectra were obtained using photons from beam line BL-8.0.1 at the Advanced Light Source in Lawrence Berkeley National Laboratory [18-20]. A Rowland-circle soft-X-ray emission spectrometer with spherical grating and a photon-counting area detector was used to obtain the SXES spectra. The resolution of the spectrometer was 0.5 eV at hν=700 eV. The energy axis of XAS spectrum was calibrated by measuring the XAS spectrum of Fe-metal. The energy axis of SXES spectrum was calibrated by peak positions of elastic scattering, which corresponds to excitation energy.

3. RESULTS AND DISCUSSION

Figure 1 shows the Fe 2p XAS spectrum of LSFO thin film. The spectrum consists of two parts derived from the spin-orbit split of L3 (2p½) and L2 (2p½) states. They are further split into the τg and e_g states due to the octahedral ligand field. The crystal-field splitting (10Dq) corresponding to the energy separation between τg and e_g states is 1.5 eV. The spectral shape, peak position, and 10Dq are similar to those of La₃Sr₂Fe₂O₉, which was theoretically calculated assuming a high-spin [t²g]³[e_g]³ ground state [21].

Figure 2 shows the O 1s and Fe 2p SXES spectra and O 1s XAS spectrum of LSFO thin film, where the abscissa is the relative energy to Fermi level (E_F). The O 1s and Fe 2p SXES spectra were measured at hν=560 eV and 735 eV, respectively. The Fe 2p and O 1s SXES spectra, which correspond to the fluorescence spectra, reflect the Fe 3d and O 2p PDOS, respectively, in the valence band. The PDOS cannot obtain from the PES spectra because the PES reflects the total-DOS at the surface state. Therefore, the detailed discussion of the valence band is possible in the fluorescence spectra. The energy position of O 2p state overlaps with that of Fe 3d state. This result indicates that the Fe 3d state hybridizes with O 2p state in the valence band. The valence band has three structures labeled A, B and C. The Fe 3d contribution is more significant in the B and C peaks. In particular, the Fe 3d PDOS is dominantly at near E_F. On the other hand, from the dipole selection rule, it is understood that the O 1s XAS spectrum of Fe oxide corresponds to transitions from O 1s to O 2p [13,22]. The conduction band has three structures. Two sharp peaks at ~2.2 and ~3.7 eV from E_F correspond to the τg and e_g states, respectively, of Fe 3d conduction band.

In the XAS spectrum of Fig. 2, h peak is observed at near E_F. Similar peak has been reported in ref. 11. This peak cannot reproduce by the tight-binding calculation. In the tight-binding calculation and spectroscopic data [10,11], the value of the band gap of the parent insulator (LaFeO₃) is estimated to be ~2 eV, which corresponds to the optical gap reported by Arima et al [2]. When holes (Sr²⁺) are doped into La⁺⁺ site of LaFeO₃, E_F moves downward and crosses the e_g band at E_F, making the system metallic if the rigid-band model can be applied. Then, hole-induced state corresponding to peak h appears above E_F. The existence of the hole-induced state indicates that the rigid-band model is no more valid, and doped holes enter split-off localized states formed by hole doping.

Figure 3 shows the comparison between the Fe 2p fluorescence spectrum and the theoretical Fe 3d PDOS calculated by Wadati et al [10,11]. Wadati et al. has studied the electronic structure of LSFO thin film by PES and tight-binding calculation. His calculation is similar to local density of approximation (LDA) + U in the sense that the effect of electron-electron interaction and hence the value of the band gap is adjusted via AE in the tight-binding calculation and via U in the LDA + U calculation. In the PES spectra, the line shape and peak position do not accord with the tight-binding calculation. This may originate other interaction for photoemission process. However, the spectral shape of Fe 3d-PDOS in the valence band obtained by the tight-binding calculation accords with the Fe 2p fluorescence spectrum. The magnitude of electron correlation energy is approximately 3.0 eV, which has estimated.
from tight-binding calculation. This value accords with the energy separation between C peak and $t_{2g}$-subband in Fig. 2. The existence of Fe 3d PDOS at $E_F$ has an important role for the MI transition of La$_{0.6}$Sr$_{0.4}$FeO$_3$. Because the bottom of the conduction band is also Fe 3d state, the electrical properties contribute to the magnitude of electron correlation energy. Thus, the SXES spectra in this study give an useful information for electron correlation.

4. CONCLUSION
The authors have studied the electronic structure of LSFO thin film using SXES and XAS. The conduction band consists of the $t_{2g}$- and $e_{g}$-subband of Fe 3d state and the hole-induced state near $E_F$ created by Sr doping. The valence band is mainly composed of the $e_{g}$- and $t_{2g}$-subband of Fe 3d state hybridized with O 2p state. The spectral shape and peak position of valence band are in good agreement with the result of electronic structure expected by tight-binding calculation that included the effect of electron-electron interaction.
