The effects of strength training on isometric force production symmetry in recreationally trained males

Caleb D. Bazzyler, Chris A. Bailey, Chieh-Ying Chiang, Kimitake Sato, Michael H. Stone

Objectives: The purpose of this investigation was to determine what effect a bilateral strength training regimen has on isometric force production symmetry and if changes in force production symmetry can be accounted for by differences in pre-intervention strength levels.

Design: Sixteen recreationally trained males (1-RM squat: 146.8 ± 23.0 kg.) were assigned to two groups for the 7-week training intervention: strong (S) and weak (W) based on pre-training squat isometric peak force allometrically scaled (IPFa) at 120° knee angle.

Methods: Subjects completed a 7-week training intervention following a block-periodized model and were tested on measures of dynamic (1RM squat) and isometric (isometric squat at 90° and 120° knee angle) strength pre- and post-intervention. The degree of bilateral lower limb asymmetry was calculated as a percentage where 0% symmetry index (SI) indicates perfect symmetry on the isometric squat.

Results: ANCOVA results showed no statistical difference between groups for all dependent variables when pre-intervention IPFa 120° scores were used as the covariate. Paired t-tests results showed both groups statistically improved 1RM squat and IPFa 120° ($p < 0.05$). IPFa 120° SI decreased statistically from pre-training in the W group ($p = 0.03$). Independent t-test results showed the W group had statistically larger pre-intervention SI scores for IPFa 90° ($p = 0.045$) and IPFa 120° ($p = 0.007$); however this difference was no longer present following strength training. There was a strong inverse relationship between pooled IPFa 120° and IPFa 120° SI ($r = -0.64$, $p = 0.004$).

Conclusions: The findings of the current study support the notion that weaker individuals can augment lower limb symmetry with strength training. The same does not seem to be true for stronger individuals who already have a low symmetry index score. These findings indicate that strength training improves force production symmetry in relatively weak males, which may be important for bilateral tasks and injury potential reduction.

Key words: bilateral ■ strength training ■ asymmetry ■ squat

INTRODUCTION

Recently, limb asymmetry in sport has gained interest among coaches and athletes and has become a more prevalent research topic.^{1,2} Specifically, the relationships between force production symmetry, injury, and performance seem to be a common interest.³⁻⁵ The lack of ability to produce symmetrical movement patterns and the inability to produce force symmetrically have been indicated as risk factors for injury, but currently there remains some doubt due to a lack of direct evidence to support this claim.^{6,7}

The role symmetry plays on performance has not been researched as extensively. Yoshioka and colleagues (4) completed a computer simulation study which compared a symmetrical and an asymmetrical model of the lower limbs during jumping tasks. The models were equated for strength, but the distribution of the strength between limbs differed. Their results showed that the stronger limb of the asymmetrical model would make up the difference in the weaker limb and

jump height would not be affected as a result. Bailey et al.⁵ reported different findings in a study measuring symmetry of an isometric mid-thigh pull. Their findings indicate a negative relationship exists between isometric peak force symmetry and both jump height and peak power during counter movement and static jumps. Thus, the relationship between strength symmetry and performance requires additional research.

Even less research has examined the role of strength training to reduce asymmetry. If symmetrical force production and strength capabilities are desired qualities, one may wish to reduce strength asymmetry by strength training. Therefore, the purpose of this study was to determine what effect a bilateral strength training regimen has on isometric force production symmetry and if changes in force production symmetry can be accounted for by differences in pre-intervention strength levels.

METHODS

Subjects

Subjects recruited were 20 recreationally trained college aged males with at least one year of resistance training experience on the squat ($\geq 1.3 \times$ body mass). Only 18 subjects were included in the data analysis; one withdrew due to injury and another was excluded as an outlier (produced values greater than twice the standard deviation of the pooled mean). The one repetition maximum (1-RM) squat indicated that the subjects were moderately trained: pre-training 1-RM squat: 146.8 ± 23.0 kg., squat to body mass ratio: 1.68 ± 0.22 .⁸⁻¹⁰ Subjects were ranked based on pre-training squat isometric peak force allometrically scaled (IPFa) identified at knee angle of 120° and divided into 2 groups, weak (W) and strong (S). Allometric scaling is based on the surface law, which states that as the volume of a body increases, its surface area reduces in proportion.¹¹ Thus, IPFa was calculated by dividing peak force by body mass raised to the 0.67 power ($N/kg^{0.67}$). Nine subjects in the W group (age 20.8 ± 2.0 years, height 176.4 ± 6.3 cm, body mass 84.9 ± 10.9 kg) and nine subjects in the S group (age 20.7 ± 1.9 years, height 177.6 ± 8.1 cm, body mass 86.1 ± 8.9 kg) completed the study. Throughout the study, subjects were instructed not to participate in physical activity 24 hours prior to testing or training sessions. Prior to participating, all subjects completed a health history questionnaire and signed an informed consent that was approved by the university's Institutional Review Board. Although subjects were not specifically questioned about previous leg injuries, they were required to report injuries that could be exacerbated by participating in the study. Both groups performed back squats $2 \text{ d} \cdot \text{wk}^{-1}$ for 12 weeks with a minimum of 48 hours rest between training sessions. Dynamic and isometric strength were measured pre- and post-intervention via 1-RM and isometric squat, respectively.

Training

After eligibility was determined by 1-RM squat testing ($\geq 1.3 \times$ body weight), subjects trained $2 \text{ d} \cdot \text{wk}^{-1}$ for 3 weeks in a strength-endurance phase to equilibrate the training program for all subjects. During this phase, subjects were familiarized with isometric squats to minimize learning effects and to record bar heights and knee angles for subsequent testing. Table I describes the 12-week training program and testing sessions. Subjects were required to complete $>80\%$ of the programmed volume load to be included in the data analysis.

Each training session began with a dynamic warm-up using only body weight, followed by warm-up sets on the squat. Groups followed a block-periodized model with heavy and light days within each microcycle to manage fatigue.^{12,13} Load for squat and partial-squat was calculated using percentage of pre-intervention 1-RM. All training sessions were supervised to ensure correct technique and safety.

Testing Procedures

Anthropometrics and 1-RM squat were measured at the beginning of week 4 and 12 dynamic testing sessions. IPFa at a 120° knee angle, IPFa at a 90° knee angle, and symmetry index (SI) scores for IPFa 120° , IPFa 90° were assessed during the isometric testing session, which occurred 72-96 hours after dynamic testing.

Dynamic Strength Assessment

Once subjects arrived, anthropometrics were measured, followed by a dynamic warm-up. 1-RM squat protocol involved a progressive increase in load and decrease in reps per set.⁸ 1-RM squat attempts were selected with the goal of reaching their max in three attempts after warm-up. Four minutes of rest was given between each attempt. Back squat depth was determined as the top of the leg at the hip joint being below the knee.¹⁴

Isometric Strength Assessment

Kinetic variables were measured on 0.45 m x 0.91 m dual force platforms affixed side by side (Rice Lake, WI) sampling at 1,000 Hz inside a custom designed power rack that allows fixation of the bar at any height, as described previously.¹⁵ Subjects performed a dynamic warm-up followed by two warm-up attempts at 50% and 75% of perceived maximal effort at 90° angle of the knee. After the two-minute rest period, two maximal efforts were performed with 3 minutes rest in between trials. The bar was placed across the back in the same position used in training and placed against two metal stops to prevent upward movement (Figure 1). The same assistant recorded knee angle and bar height for all testing sessions. The tester instructed subjects to push as fast and as hard as possible.¹⁶ The tester shouted 'push' and participants pushed maximally into the ground until peak force was reached when the tester shouted 'stop' to end the test. After completing testing at 90° subjects were given 5 minutes rest and the same protocol was repeated at a 120° knee angle. Subjects were tested at the same time of the day for both test days.¹⁷ SI was calculated using the following equation:

$$SI = 100\% \times (\text{Larger value} - \text{smaller value}) / \text{sum of values}$$

(Shorter, Polk & Rosengren *et al.*¹⁸ ; Sato & Heise¹).

The resultant is a percentage where 0% indicates perfect symmetry and the level of asymmetry increases as the value gets further away from zero. The force-time curve data were

smoothed using an 11-point moving average (all data points equally weighted) and analyzed with Labview software (ver. 2010, National Instruments, Austin, TX, USA). The average of two attempts on the isometric squat at 90 and 120° were used for analysis.

Statistical Analysis

A Shapiro-Wilks normality test was used to determine if the data were normally distributed. A Levene-test was used to determine homogeneity of variance. Intra-class correlation coefficients (ICC) were calculated to determine test-retest reliability. As a result of the statistical difference between groups for pre-intervention IPFa 120° scores, a univariate analysis of covariance (ANCOVA) was used to assess differences between the two groups post-intervention for all dependent variables. Paired sample t-test and independent samples t-test were calculated to determine within and between group differences for dependent variables. A Pearson's product-moment correlation was used to assess the relationship between dependent variables. For all tests the alpha level was set at $p < 0.05$. SPSS software version 21 was used to perform all statistical analyses (IMB Co., NY, USA).

RESULTS

Dynamic Strength Assessment

1-RM Squat

After adjusting for pre-intervention scores, ANCOVA results showed no statistical difference between groups for 1-RM squat post-intervention. The mean values for 1-RM squat in S increased from 167.57 ± 26.44 to 175.99 ± 26.44 kg ($p < 0.001$, +5.0%) and in the W from 137.84 ± 19.10 to 146.91 ± 17.67 kg ($p < 0.001$, +6.6%).

Isometric Strength Assessment

Isometric Squat Peak Force Scaled Symmetry Index

After adjusting for pre-intervention scores, ANCOVA results showed no statistical difference between groups for IPFa 90° SI or IPFa 120° SI post-intervention. Paired t-test results indicated that IPFa 120° SI decreased statistically from pre-training in the W group ($p = 0.03$); however, IPFa 90° SI showed no statistical change in either group. Independent t-test results showed a statistical difference between groups pre-training for IPFa 120° SI ($p = 0.007$) and for IPFa 90° SI ($p = 0.045$) with the W group being statistically greater than the S group; these differences between groups were not present following strength training. IPFa 120° statistically increased in both groups ($p < 0.05$), whereas only the S group statistically improved IPFa 90° ($p = 0.01$). There was also a strong inverse relationship between IPFa 120° and IPFa 120° SI ($r = -0.64$, $p = 0.004$). Test-retest reliability using ICC for IPFa 90° and 120° was 0.98 and 0.98, respectively. Mean and standard deviation for dependent variables are listed in Table II.

DISCUSSION

The findings of this study indicate that there is strong inverse relationship between isometric strength and bilateral lower limb asymmetry and that weaker individuals can augment lower limb symmetry with strength training. Although changes in lower limb asymmetry as a result of strength training have not been researched extensively, some research findings support that strength imbalances increase injury risk.^{3,6,19} However, there is still a lack of consensus on what a normal imbalance is and how much deviation is acceptable.²⁰ The current findings indicate that strength training can decrease lower body muscle imbalances, agreeing with the available previous research. Golik-Peric and colleagues found that 4 weeks of isoinertial and isokinetic training in athletes improved ipsilateral muscle symmetry by increasing the concentric hamstring to quadriceps torque ratio (conH/Q). In their study, athletes were divided into an isokinetic and isoinertial training group. After completing a 4-week training program, the isokinetic and isoinertial groups increased the conH/Q ratio by 25.4% and 13.0% on the right lower limb, respectively.²¹ In comparison, the results of this paper showed a 51.5% reduction in contralateral lower limb asymmetry in the weaker group at a 120° knee angle. The larger percent changes in our study are likely related to the longer duration of the training program (7-week intervention). Similarly, Impellizzeri and colleagues (2007) showed a 56.5% decrease in bilateral vertical jump force asymmetry following anterior cruciate ligament reconstruction and 7-9 weeks of physical therapy programs.²²

The subjects in the current study were not collegiate athletes, but they did exhibit strength levels equivalent to and greater than previous research with some athletes.⁸⁻¹⁰ Although both groups statistically improved 1-RM squat only the weaker statistically decreased strength asymmetry, indicating that gains in bilateral strength may only decrease lower limb asymmetries to a point. Whether or not the decrease in asymmetry in the weaker group was directly responsible, independent of bilateral gains, for enhanced performance on the isometric squat or 1-RM squat is beyond the scope this study. However, it can be surmised that strength training improves force production symmetry in relatively weak males, which may be important for bilateral tasks and injury potential reduction.

CONCLUSION

The findings of the current study support the notion that as lower limb strength increases there is a concomitant decrease in asymmetry in weaker individuals. The same does not seem to be true for stronger individuals who already have a low symmetry index score. The decreases in asymmetry found in the weaker group may have implications for bilateral movements requiring symmetrical force production. Future research should address what is a normative symmetry index score, do larger asymmetries result in decrements in performance and increased injury risk, if so, identifying the magnitude of asymmetry can be an important issue for further investigation.
